Since the paper of Dr. Nichols of Boston, in 1898, it has become the custom in America to regard all cases of joint tuberculosis as due to a bony focus. It has been said that with a growing pathological experience the cases one regards as primarily synovial become fewer in number. This possibly is true, and it is also true that unless all the bones entering into the formation of the joint have been sawn into very small pieces, the objection can plausibly be raised that a bony focus can easily have been overlooked. But, on the other hand, if all the articular ends of the bones, sawn across near the joint, present no evidence of any involvement, and if the synovial membrane in its entire extent and in its entire thickness is filled with tuberculosis, the possibility of primary synovial tuberculosis must be seriously considered. Again, it seems unlikely that a tuberculous process, starting in the bone, would make its way directly to a joint, and involve the entire synovial membrane without spreading at all in the bone. Often in the cases known to be primarily bony, the superficial layers alone of the synovial membrane have been involved, as would naturally happen if the disease broke through into the joint from outside, while in the primary synovial type the membrane is involved in its entire thickness. This rule, however, is only a general one. There is nothing improbable in a synovial origin of the disease. We have a specimen here of tuberculous tenosynovitis, which seems not to differ in any essential respect from synovial tuberculosis anywhere. This certainly appears to be a case of primary synovial involvement. One of the specimens in the collection is a knee removed from a patient who had had the other leg amputated for tuberculosis of the ankle at the Roosevelt Hospital four months before. She had had several operations performed during her previous stay in the hospital and no mention had been made of any symptoms in this knee. The entire synovial membrane in the specimen is full of tuberculosis, but the bones appear absolutely normal.

Of our thirty-four tuberculous cases, seven (aged 64, 18, 20, 12, 21, 20, and 32) are evidently primary bony tuberculosis, four (aged 50, 17, 27, and 25) primary synovial, four probably bony; and of the other nineteen cases the origin is unknown. Nothing characteristic appears from a study of the ages of these patients.

Pathology.—Primary Bony Type.—The disease begins with a tuberculous infiltration of the marrow of the epiphysis of one of the bones, in a young patient usually at or near the epiphyseal line. This makes its way towards the joint, attacking the bone on its way. In one of our cases the bone destruction was in a piece large enough to form a sequestrum easily recognizable by the naked eye; in others the bone trabeculæ were killed in small pieces, and could be felt as bone sand. Usually, the disease travels down to the cartilage and breaks through it into the joint, or spreads out in a layer under the cartilage (mushrooms, so to speak), and enters the joint at its periphery or lifts the cartilage off en masse. Sometimes it makes its way to the surface of the bone and travels under the periosteum to the joint. (Fig. 4.) It appears that when the disease breaks through into the joint, adhesions are often formed which shut off part of the joint and protect it from invasion.

The cartilage enjoys a certain amount of immunity as long as its nutrition is unimpaired, and affords considerable protection to the joint against invasion. After the joint has been entered, the tuberculosis attacks the synovial membrane, and then the other bones entering the joint, usually at their sides, where they are free from articular carti-

lage. It spreads under the cartilage in a layer, destroys its nutrition, and loosens it from the bone either in one piece or in small pieces. At the same time, though to a less extent, the tuberculous tissue grows in from the side over the articular surface of the cartilage, forming the so-called pannus. The joints in our collection show all stages of the process. In some the cartilage is gone over the opposing bone ends, and bare bone is apposed to bare bone. In some, the denuded areas have become firmly attached to each other in places; in some, remnants of the articular cartilage can be seen. In the knee, sometimes the cartilages over one condyle and the opposing surface of the tibia are gone, and the bones are tightly bound together by connective tissue; while on the other side of the joint the cartilages and bone ends are almost normal. In the hip the head of the femur in the early stages looks

FIG. 4.—Bone tuberculosis, showing the spread of the tuberculous process under the periosteum and cartilage; specimen from the external condyle in a 12-year-old child. The joint is not yet involved; × 8 diameters. A, articular cartilage; B, epiphysis; C, epiphyseal line; D, periosteum; E, area of tuberculosis.

worm-eaten over its entire surface. Later on, this denuded, worm-eaten head may become tightly adherent to the acetabulum. More often it is ground away, and its free end lies in a collection of fluid.

Under the microscope the tuberculosis can be seen involving the ends of the bone to a greater or less extent—typical miliary tubercles, round cell infiltration, epithelioid cells, giant cells, areas of necrosis, etc. In several a distinct sequestrum can be seen, with a wall of fibrous tissue about it, more or less complete. In some the trabeculæ, showing evidences of rarefying osteitis, lie embedded in granulation tissue or surrounded by pus cells—bone sand. The bone in the vicinity of the affected area often shows signs of rarefying osteitis, often of productive osteitis, often of both. In some specimens much fibrous tissue has been formed in and about the tuberculous area, showing nature's effort at repair, in some very little. At the joint the process often appears as a layer of tuberculous tissue under the cartilage. Sometimes the cartilage is covered with a layer of fibrin; sometimes it is fibrillated, and roughened on its free surface, detached in places from the diseased bone beneath it. Again, the bones are covered with fibrous tissue, more or less infiltrated with tuberculosis, perhaps containing islands of cartilage, perhaps undergoing necrosis at its surface. Sometimes the process is in the stage of repair, the cartilage nearly or quite gone, only a few areas of tuberculosis present, and the heads of the bones covered with fibrous tissue. Fibrous connective tissue seems continuous with the cartilage, the fibers appearing to spring from it and run into it. In one specimen a small area of calcification can be seen, surrounded by fibrous tissue, as if an original spot of necrosis had been healed in this way. Areas of active disease and of healing can often be seen in the same specimen. In many of the specimens obliterating endarteritis is a well-marked feature of the process.

Primary Synovial Type.—In these cases the synovial membrane is thickened and thrown into folds. It can be seen by the naked eye, on section, studded with tubercles, and is usually affected in its entire thickness. Sometimes it is so increased in thickness as almost to hide the articular cartilage from view. The cartilages in the earlier stages are smooth, but soon a layer of fibrin is deposited on them, and the tuberculosis, making its way into the bone at their margins, spreads out under them, destroys their nutrition, and separates them. The further course of the disease then seems to be as in the bony type, and in the majority of our cases it has involved so much of the tissues of the joints that its origin cannot be told with certainty. On the other hand, the disease can exist for years in the synovial membrane and show absolutely no tendency to involve the bone. One such case was under the writer's treatment for about five years before coming to resection. The bones in this knee were normal, and the synovial membrane had been almost replaced by fibrous tissue, but in one spot presented a small area of tuberculosis about 1 centimeter in diameter. Examination of a specimen of the synovial membrane taken out one year previously had simply shown enlarged villi.

In another case, though the joint is almost destroyed, tuberculosis can only be detected by the microscope in one slide out of a number from different parts of the joint. In one or two similar instances we think the disease was tuberculosis, though we cannot demonstrate it with the microscope.

It may seem premature from so small a number of specimens to attempt to deduce any rules of procedure in the treatment of tuberculous joints; but even a small material sometimes justifies a working hypothesis, provided one does not cling too tenaciously to the theories one draws from it.

One of the first things to attract attention in these specimens is the effort of nature, as soon as tuberculosis appears in or near a joint, whether in the bone or in the synovial membrane, to deprive it of motion, to destroy it, in other words, as a joint, and to convert it into a synostosis. When this has been accomplished the disease dies out. In a resection we can never be sure of having removed every vestige of tuberculosis; indeed, the chances are strongly against our doing it, yet if we get union of the wound by first intention, we expect to cure the disease in that locality. In other words, when

we destroy the joint, the disease dies out. In none of our specimens had a complete synovectomy been done. They, therefore, cannot indicate whether this operation will have the same effect in the synovial type. We know that the disease often spreads in under the cartilage, often ceases to be purely synovial; but nothing in this collection helps us to tell whether an early removal of the synovial membrane will cause the disease to die out in the bone, as the removal of the bones causes it to die out in the remnants of the soft parts. Possibly, hereafter, in treating tuberculous joints, less effort will be expended in preserving motion, and more in obtaining ankylosis. We shall not dread the wearing away of the joint cartilages, but shall rather encourage it. We have seen under the microscope how nature attempts to destroy the affected joint. We have thought for a long time that the crowding of the bone ends together by muscular spasm tended to the same thing, and have expended all our efforts to overcome it, instead of regarding it as one of nature's efforts at cure. Some years ago Lorenz advanced the idea that he preferred a stiff joint after tuberculosis to one with a small amount of motion, because the former was more comfortable. I agree with him, and now go a step further and suggest that the best way to cure a tuberculous joint is to deprive it of motion. There is nothing striking in this theory. We used to combat fever as a thing to be dreaded, now we regard it as a conservative process.

The conservative treatment by weight bearing and immobilization—that is, by plaster-of-paris, in disease of the knee and hip seems more in line with this theory than the older method of stilting and traction. Certainly, after one has resected a few hips that have been treated by extension up to the time of operation, and has found the head of the femur lying in a collection of pus, he cannot but think that the traction treatment can be overdone. On the other hand, it is well not to be over-zealous in removing bone, not to be too careful to go "wide of the disease." It is well not to read up beforehand a particular form of operation, and then to carry it out on the joint without regard to what is found at the time of operation. Two cases of our series, hip-joint excisions, illustrate this well. From an examination of them it appears that the removal of the head of the femur alone would have sufficed to cure the disease, and would have given a better functional result, yet in both the whole upper end of the bone was removed. In one case it is hard to see of what use the extremity can be to the patient. Head, neck, and both trochanters were removed, although the bone was involved only at the circumference of the head.

A theory that has been weakened by a study of these specimens and of the histories of the patients from whom they were taken, is in regard to the mortality. Most of the patients were adults, and a rather widespread notion exists that the expectation of life in an adult with a tuberculous joint is quite short. We have been unable to trace very many of the cases up to date, but it can be seen from our histories that those we have found have established a rather low percentage of mortality. Two of the adult cases have died. The larger number of them are in health, and are earning their living. One patient seems to have acquired a sort of constitutional immunity to the infection while exhibiting a marked local predisposition to it. He has lost, by operation for tuberculosis, his testicles, seminal vesicles, part of his sternum, and seventh rib.

A most cursory examination of these joints will convince anyone of the futility of the operation of curetting as usually practised. A tuberculous process involving a synovial membrane in its various folds and ramifications, and running up under the joint cartilage into bone, perhaps with a distinct bony focus, is not to be eradicated by blindly thrusting a sharp spoon into the joint and scraping away at random.

From a perusal of the histories it appears that after some of the operations drainage was used for a few days, and after others it was not. As a general thing it does not seem necessary.

Nothing said in this paper is to be interpreted as advising resection of a joint in a child. It is far better to take long chances of life and death than to do that.

It is difficult in a short paper such as this to do more than touch upon the various instructive points that the specimens present; and, in fact, any investigation based upon so few cases can only be a preliminary one. We hope to have the opportunity to add a great many more to the series, and to carry the work forward where it will be of real service.

The main points which we have tried to bring out are:

1. The possibility of error in diagnosis.
2. A general idea of the pathology of joint tuberculosis.
3. Nature's attempt to heal the disease by ankylosis.
4. The wisdom of imitating nature in our treatment.
5. The necessity of adapting the operation to the individual case, and of only removing enough tissue to secure ankylosis.
6. The frequency of primary synovial tuberculosis.

201 West Fifty-fifth Street.

TUBERCULIN FOR THE DIAGNOSIS AND THERAPY OF RENAL TUBERCULOSIS.*

By DR. WILHELM KARO,

BERLIN.

Gentlemen, when I was asked to address your society to-night, it was my desire to find a subject which would be of equal interest to you all, in whatever branch of medical science you may be especially interested. As such a subject I consider tuberculosis, for tuberculosis is, as you know, a universal disease, one to which any part or organ of the human body may be subject. It is, therefore, necessary for the specialist to cooperate with the general practitioner, to find out what part the tuberculosis of the organ coming under his special treatment plays, in connection with the same disease affecting the other organs. In many cases tuberculosis of the kidneys is combined with tuberculosis of the lungs or of other organs; in such a case the urologist and the general practitioner must decide together in which part of the body the tuberculosis originated. This question is, of course, of the utmost importance for the treatment of a given case. For instance, we should not venture to operate upon a case of tuberculosis of the right kidney, if it is only the conse-

*Read at the meeting of the Anglo-American Medical Association of Berlin July 3, 1909.

quence of a far-advanced state of tuberculosis of the lungs.

In order not to detain you too long with this one subject, I shall not enter into the details of the diagnosis of renal tuberculosis. I will only mention the fact that, in advanced stages of this disease, an examination of the urine will confirm or correct our diagnosis. In nearly all cases we shall find pus and tubercle bacilli in the centrifugated urine. If no bacilli are found, then we must resort to the inoculation of guinea pigs. This matter has been simplified lately by Bloch; he has taught us to inject the urine, to be examined, into the compressed inguinal glands. In this manner we can learn within ten days or two weeks whether or not the urine contains bacilli. Should this test show that no bacilli are present, it would by no means prove that the disease is not tuberculous. In such a case we must bear in mind that the diseased ureter may have been temporarily obliterated and that the urine examined was that of the healthy kidney.

On the other hand, there are cases in which in the very first stages of tuberculosis no bacilli are found, because the process is confined to a very small spot at the top of the kidney, having no connection with the glomeruli. It is, therefore, not permissible to make the diagnosis of renal tuberculosis dependent solely upon the finding of bacilli, and it would be of great advantage for us to add one factor more to our diagnostic resources.

Can tuberculin be looked upon as such a help? As you know, there are four different ways of making such a specific diagnosis: The v. Pirquet reaction, the Moro reaction, the conjunctival test and the subcutaneous injection of tuberculin. The v. Pirquet reaction is, as you know, applicable only to children; and concerning the ointment reaction of Moro, I am lacking in personal experience.

In applying the conjunctival reaction we must always bear in mind that a positive result only proves the presence of some tuberculous focus in the body, and I have already emphasized at the beginning of my lecture how frequently the urogenital tuberculosis is a secondary affection. I repeat, renal tuberculosis may be propagated by the blood or lymph from other foci in the lungs or the bronchial glands. In spite of the most exact clinical investigation we might not be able to exclude glandular tuberculosis. The following very instructive case will demonstrate clearly how deceptive the positive result of the conjunctival reaction may be in regard to the local diagnosis. At Professor Casper's clinic I observed last year a lady suffering from pyuria and pain in the right kidney. It was reported that the family physician had occasionally found some tubercle bacilli in the urine, but we were not able to confirm this. By a thorough cystoscopic and functional examination the right kidney proved to be the source of pyuria. The ophthalmoreaction was distinctly positive. As no other diseased focus could be found, we diagnosed tuberculosis of the right kidney. We were therefore highly surprised to find at the operation not a trace of tuberculosis. Instead the cause of the pyuria proved to be twelve calculi. I think, gentlemen, this case shows quite obviously how justifiable the statement is that a positive ophthalmo reaction may be rather a misleading guide, especially as similar cases have been reported by other authors.

On the other hand we observed cases showing a negative ophthalmo reaction which were nevertheless tuberculous. As an example: I observed a lady of twenty-eight years of age who had suffered from her childhood with cystitis. Some years before I saw her she had undergone a suprapubic operation for a contracted bladder. We found an intense pyuria, but no bacilli whatever. On cystoscopy and catheterization of this ureter the left kidney appeared to be healthy. The right ureter could not be found in spite of repeated cystoscopy; we only ascertained that the right half of the trigonum was strongly ulcerated and incrustated with crystals. The ophthalmo reaction was negative. In order to ascertain an exact diagnosis we exposed the right kidney and found a very small infantile kidney with an entirely obliterated ureter. The kidney itself showed a typical miliary tuberculosis.

The same failure of the ophthalmo reaction was experienced in the third case. This concerns a young boy suffering from severe pain in the left side and pyuria, and a suspicious swelling of the left knee joint. In the centrifugated urine we could not find any tubercle bacilli. By cystoscopy the bladder was found to be healthy; the function of both kidneys was practically normal. The ophthalmo reaction was also in this case negative. By an animal experiment, however, with the urine of the left kidney, tubercle bacilli were detected. Here a renal tuberculosis was present, in spite of a negative ophthalmo reaction. I think, gentlemen, these few cases, to which other personal observations and cases of other authors could be added, justify my statement that the ophthalmo reaction is no aid at all in an exact differential diagnosis.

In contradistinction to the eye test, the old subcutaneous tuberculin test seems to me indeed a very valuable diagnostic means. Above all, this test has the peculiarity of giving us a local reaction, that is to say a reaction confined to the localization of the tuberculous focus. For instance, if a tuberculous process is located in the left kidney the patient will notice some pain in this region a short time after the injection. It is obvious that such an advantage renders the method invaluable for the majority of cases. For this I am also able to give you an instructive case. A few months ago I was consulted by a young girl suffering from pyuria and pain in the right renal region. The urine was slightly turbid, and contained typical tubercle bacilli. By cystoscopy the bladder appeared healthy, only the opening of the right ureter was slightly swollen. The function of both kidneys was equally normal; the indigocarmin injection gave a prompt secretion of blue urine of equal intensity on both sides. From the right kidney purulent urine containing tubercle bacilli was secreted. The left kidney was considered normal, and therefore not examined.

After a subcutaneous injection of one-quarter mg. Alttuberkulin the patient got severe pains on both sides, but more severe in the left kidney than in the right. At the same time the urine became much more cloudy and contained considerable amounts of epithelium and tubercle bacilli. After the reactive symptoms subsided, I catheterized the left ureter, too, and found numerous tubercle bacilli here also.

This case therefore illustrates very clearly that the subcutaneous injection led us to the right diagnosis of the bilateral renal tuberculosis. We could certainly have catheterized also the left ureter at the very beginning and might have recognized the affection of both sides. As, however, this would have required several animal experiments and had taken

much more time, I chose the shorter way of the tuberculin test and then confirmed the result of the injection by a microscopical examination.

The great advantage of the subcutaneous reaction is that it allows us to draw conclusions not only as to the specific affection, but also the location of the process as well. This advantage, gentlemen, renders this test far superior to the ophthalmo reaction. Though the general reaction may sometimes be severe, permanent disorders never have been observed as a result of the injection. I shall always, therefore, prefer this test to all other diagnostic means, and wish to emphasize that in the examination of a suspicious case the subcutaneous injection should be the first step in our investigation.

Tuberculin has become of far greater importance in the conservative treatment of urogenital tuberculosis. You all know how much the failures of the first era of tuberculin-therapy disappointed the practitioners. But on the other hand the experiences of the last few years have taught that it was only a wrong method that had led to the failures, and tuberculin itself should not be held responsible for them. For we have learned that all depends upon two main factors, that is, regulating the method according to the resistance of the patient, and the most careful dosage of tuberculin. After we began to consider these two points very carefully, the results have justified the method, and again a wide field of work has been opened to the general practitioners.

Besides Lenhart and Pielicke, who have first reported very favorable results with the tuberculin treatment of renal tuberculosis, recently an English surgeon, Leedham-Green, has also advocated the conservative treatment in the early stages of the disease. I must confess that I have assumed the standpoint of an extreme radicalism; not more than one year ago I spoke here in your society in favor of this view, and in the International Congress for Tuberculosis at Washington I stated that tuberculosis of one kidney is an absolute indication for the radical interference. Personal experience has now induced me to change my standpoint. I have had to treat renal tuberculosis repeatedly with tuberculin, and as the result of this work I have been compelled to give up my former view.

I wish to give you a brief account of these cases:

In the first case, we had to deal with a girl of 8 years of age, suffering from pyuria and painful micturition; the bladder was cystoscopically intact; only at the right ureteral opening there was a small tuberculous ulcer; from the right ureter a purulent urine containing tubercle bacilli was secreted. I proposed an operation, but the parents would not consent, and suggested a tuberculin cure.

The patient got altogether 30 injections of Alttuberkulin Koch in the concentration suggested by Holdheim; that is to say, beginning with 0.0025 mg. Alttuberkulin, increasing slowly up to 10 mg. The result was excellent. The child improved and gained 18 pounds in weight within five months. Six months later I found a completely normal bladder and the urine quite clear without any tubercle bacilli. The catheterization of the right ureter gave also clear urine without any albumen or bacilli. The future will teach us whether the girl is definitely cured; at any rate we have accomplished enough to be able to say that dispensing with the operation did not do any harm to the patient.

My second case concerns a nurse 23 years of age. under my treatment for tuberculosis of the right kidney. Cystoscopic examination showed a tuberculous ulceration at the opening of the right ureter; from this kidney a purulent urine containing tubercle baccilli was secreted. As the patient did not consent to an operation, I was obliged to start a tuberculin treatment, and I was greatly surprised to notice a gradually increasing improvement both subjectively and objectively. Within six months I made 25 injections; she gained 25 pounds in weight; the tuberculous process in the bladder has entirely disappeared. The urine is still somewhat cloudy and contains a few tubercle bacilli.

As my third case I mention that of a child of about twenty months under my treatment only for the past ten weeks.

There was a slight enuresis, pyuria, and tubercle bacilli in the urine; the right renal region was tender. I started a very careful tuberculin treatment. Up to date I have given ten injections; after the third injection the enuresis ceased. The little girl is in the best state of health, has gained eight pounds in weight. Tubercle bacilli have not been found in the last two examinations. A definite conclusion about the result is not, of course, so far possible, though I do not hesitate to predict a good prognosis also in this case.

My last case is just as little conclusive as to the final result. It refers to the case mentioned in the first part of my lecture. This young girl with the bilateral renal tuberculosis has been too short a time under my treatment for me to be able to speak of it as a success. She has not received more than six injections; nevertheless, I can state that she has increased eight pounds in weight, the micturitions are less painful and not as frequent as before.

So much for my personal experience. As, however, my observations have only been extended over a period of about eight months, I would not dare to speak of a definite cure. Nevertheless, these cases prove that it is no longer justifiable to maintain the statement that it is absolutely necessary to proceed at once to an operation.

The important question is: Which cases are suitable for tuberculin treatment? I am of the opinion that with the exception of those cases in which there is a special reason for us to operate immediately, such as fever, etc., we may with perfect safety try a systematic tuberculin treatment. Operation is only necessary in cases where this treatment has proved a failure. This delay is absolutely without any danger for the patient. We are all the more justified to start a tuberculin treatment, as even the most thorough clinical investigation is unable to inform us as to how far the disease has progressed.

In a far advanced case we will probably be obliged to operate, but that does not exclude the advisability of first attempting a tuberculin treatment. The most important thing is, therefore, an early diagnosis, and it is just for this reason that I have called your attention to the accuracy of a specific diagnosis by tuberculin injection.

Even in cases requiring an operation, tuberculin is of the utmost importance for the after-treatment; above all for the complete recovery in cases showing an involvement of the bladder. We have again and again become convinced that in all cases that have been treated with tuberculin after the operation the bladder symptoms healed much quicker than in cases in which no tuberculin was applied. I am convinced that for this reason tuberculin will

prove indispensable in the treatment of all cases of tuberculosis of the urinary organs; and, in conclusion, I should be very pleased if this paper should be the means of attracting your attention to the specific, conservative treatment of renal tuberculosis.

THE TRAUMATIC NEUROSIS AND BABINSKI'S CONCEPTION OF HYSTERIA.*

By TOM A. WILLIAMS, M.B., C.M., EDIN.,

WASHINGTON, D. C.

The significance of the new doctrine of hysteria in the interpretation of the mysterious traumatic neurosis has not received the attention it deserves. An editorial communication pointing out its far-reaching implications received little attention in this country until the following letter reached me; and it is to meet the objections therein brought forward against the thesis that the considerations which follow are here presented:

"The ideas expressed in your article, 'Recent Advances Regarding Hysteria in Relation to Traumatic Neurosis,' and, in fact, the whole attitude of the Babinski school, are of a novel and even of a somewhat startling character. Although you do not specifically affirm it in your paper, the implied deductions from your conclusions seem to be a denial of the very existence of the traumatic neurosis, or a denial that any necessary connection of cause and effect exists between an injury not sufficient to produce structural alteration of the nervous system and the development of the hystroneurasthenic syndrome, which has been styled the traumatic neurosis. If I understand your opinion correctly, it is that every case of traumatic neurosis arises from some suggestion either venal or ignorant upon the part of a medical atendant or other person coming in contact with the patient subsequent to the injury. There are two highly important aspects of this hypothesis to which I take the liberty of adverting. In the first place, does it change the practical aspect of the case to assume that suggestion must intervene after trauma to produce the neurosis, if the trauma must exist to establish the susceptibility to suggestion? A severe trauma, with all its attendant phenomena of horror, fear, and pain, is quite sufficient, I should suppose, to take the place of suggestion or afford the suggestion itself. It seems to me that even if the suggestion is always heterogeneous, the responsibility will not be shifted unless injury is always to be regarded as incapable of producing any effects whatever except those of a demonstrably histological or organic nature. Will those who are to mould the neurological thought of the future insist that this is the case?

"The second aspect of the question which appeals to me is its broad generality. It admits of no exceptions. The science of neurology, though it has accomplished wonders in unraveling the mystery of the nervous system, is in no position to acclaim so surprising a generalization. To be sure, there are many cases where suggestion, if it does not originate, at least accentuates the picture of the traumatic neurosis. But to say that, in every single case where the syndrome exists, it has originated in an externally imposed verbal suggestion is to totally deny and exclude the effect of shock as an element of suggestion. In your excellent paper you ascribe, as it seems to me correctly, the state of increased susceptibility upon which hysteria depends to the three great factors: faulty education, cerebral modifications, and hereditary constitution. But this does not necessarily deny to shock which may actually produce intense and characteristic functional disturbances a right to stand, directly or indirectly (and to my mind more likely directly), as a sufficient cause for the production of a state of psychic hypersusceptibility along with, or in conjunction with, the other factors mentioned by you. In other words, the traumatic neurosis develops upon the soil of traumatic hypersusceptibility, and consequent verbal suggestion is secondary and may not even exist. This brings me up to the final question as to whether or not trauma itself may act as the principal if not the unique element of suggestion in the development of a neurosis. This, it seems to me, can only be decided by the immediate isolation of the injured. If the traumatic neurosis fails under these circumstances to develop, then the position of the modern French school headed by Babinski will be more difficult to controvert."

In the first place, the fact that they are novel and even startling is no just cause to reject ideas. Secondly, the suggestions of which I spoke need by no means reach the patient subsequent to the trauma; nor does it need a trauma to establish susceptibility to suggestion; nor do horror, fear, and pain always accompany injury, and when they do so they need not necessarily afford any suggestion, and certainly cannot replace one. Of course, injury may produce emotion: but this is evanescent, unless perpetuated ideationally; for even shock does not suggest, but merely fortifies a suggestion if given; and this, as will appear, need not be "externally imposed verbal suggestion." The word "shock" is used by this writer in the psychological sense; and the psychic hypersusceptibility it connotes is a very minor matter compared with the "other factors." The suggestion must exist, is usually primitive and not secondary, and need be neither "subsequent" nor "verbal." Isolation from suggestion, including antecedent influences, does prevent traumatic neurosis.

To show the connection of cause and effect between the hysteroneurasthenic syndrome and an injury not sufficient to produce structural injury to the nervous system, the best plan is to quote and comment upon such cases as the following:

Some time ago (1889) there was a railway accident in this country[1] in which out of 265 passengers 123 were wounded. Out of this number only two sustained severe injury to the nervous system and neither of these subjects suffered from traumatic neurosis. Twenty-four persons complained of injury to the spinal cord, and their statements were affirmed by medical witnesses. Putting aside the simulators, of which there were several, the others were treated by medical men who believed their patients to be suffering from some serious but obscure injury and who did not hesitate to affirm to their patients and their friends that the malady was of a dangerous nature.

The following particular case is a good example: It is that of a man who had not been externally injured, and who undertook a journey of 200 miles immediately after the accident. The next day on arriving at his house he became stiff and complained of pains. His wife called in the doctor, who informed the patient that he was suffering from Ehrichsen's disease and that he must remain in bed

*Communication made to the Second International Congress on Industrial Accidents, at Rome, May 23-27, 1909.

for five or six weeks. He went to bed and took enormous doses of bromide and choral; applications were also made to the spinal column. The patient had been in business but had failed. The drugs and the confined life produced a loss of weight and strength, and his general health became impaired. Three months later Dr. Bevan saw him. He pretended to have lost his reason and that the lower limbs were paralyzed. But Dr. Bevan took him out of bed, and persuaded him, with his help, to walk round the room. He recommended him to get up and take exercise, assuring him at the same time that he was not injured, and that he could be cured, if he wished it, in a month. He replied: "My doctor told me I would always be an invalid and you tell me that I am not ill at all; who must I believe?" Six months after the accident the suit was brought against the railway company. The proceedings were hastened, the death of the patient being feared. The patient claimed damages on the ground of permanent injury to the spinal cord. The proofs were made before the judge by the dynamometer, the esthesiometer, electricity, etc. He was given a large sum of money as compensation. A short time after he took up his work again.

Another case is that of a man who had no external injury, but who was greatly frightened, a typical case of traumatic hysteria. He, too, called in Dr. Bevan. He complained of a severe pain in the back and claimed that the lower limbs were paralyzed. At the end of a week the doctor took him in his arms and made him stand up, assuring him at the same time that he was not injured, only frightened. He cried like a child. In ten minutes he was persuaded that he could walk. He left the hospital three weeks after the accident. Shortly after leaving he consulted a neurologist, who told him he was suffering from a "commotion" of the spinal cord. Dr. Bevan then sent him to another medical man to whom he had already written his opinion of the case. This doctor thereupon advised the patient to commence work again, and he did so. After he was cured he was very grateful for the treatment, although at the time it appeared very severe. As he admitted, he was so thoroughly frightened that if he had been told he was suffering from an injury of the spinal cord he is certain he would have become a chronic invalid.

Each of these cases shows that mere exhortation and compulsion quickly removed an inability to walk, supposedly due to some organic perturbation. Now, we have no evidence to show that either pathological exudates or abnormal arrangement of cell processes or static changes in the equilibrium of the Betz cells in the psychomotor projection area can be affected by exhortation; while we have strong evidence to show that exhortation and compulsion can induce or remove false fixed ideas as to motor and intellectual incapacity. But not only that, they can influence the emotions, which in turn, in course of time, profoundly modify nutrition; for the experiments of Pawlow[2] have shown how important is the psychic factor where the salivary and gastric secretions are concerned. Anxiety, worry, grief, are all forms of fear which inhibit these secretions. But not only are noxious substances produced in the stomach through the fermentation permitted by the delayed digestion there, but the retardation in the outflow of acid chyme interferes with the hormonic activities which are required for the outpouring of pancreatic and biliary fluids, as shown by Bayliss,[3] The effects of this malnutrition and intoxication are seen in the yellow tint, emaciation, indicanuria, and other neurasthenic symptoms which the traumatic-hysteric eventually develops.

The so-called gastric neuroses are striking examples of this fact. They are cured by the removal of the patient's idea that his food will disagree; for it is only when this is done that he will normally digest it; for when each morsel reinforces the dread and its inhibitory effect upon the gastric secretion, the food really does disagree, until from the vicious circle established, emaciation may become so profound that death may follow.

In the hit-or-miss therapy of unreasoning negation of all physical agencies employed by the Christian Scientists, these are among the patients who are cured. But though the cause of this disease is psychic, it it not necessary that it be cured by the substitution of one delusion by another. For confinement to bed, and the observation for a few weeks of his gain in weight, from which he cannot but infer that he must be digesting his food, when added to the true explanation of his condition gradually inculcated by his physician, is not only a more certain and permanent method of cure, but obviates the intellectual disorientation and disharmony with the universe connoted by a superstition. That the gastric neuroses are generally induced, or at least perpetuated, by the unskilled suggestions by medical men is clearly shown by Déjérine,[4] and Bernheim,[5] The unwary remarks doctors use before patients who consult them for indigestion, and their ignoring of the mental factor in dyspepsia, and of the laws of suggestibility, must be blamed for this.[6] The analogy with the traumatic neuroses is complete: both are hysterical symptoms in the sense of Babinski[7]; for both are "induced by suggestion and removed by suggestion-persuasion."

Trauma is quite unnecessary, as shown by such a case as that Dubois[8] reports, where a peasant boy, in the hospital for a trivial ailment, was told before the class that he would be unable to lift his right arm; and he could not do so until Dubois declared that a certain maneuver would give him the power; the boy then quickly raised his arm. Bernheim's writings swarm with such cases, in which paralysis, anesthesia, or other incapacity is merely the expectation, the fervent belief, of the patient in his own incapacity. An exactly similar fervent belief is present in the popular mind that certain traumata produce certain disabilities, which accordingly manifest themselves in hysterical individuals.

The source of the belief in Dubois' boy was easy to see, because experimental; while the source of the popular belief is buried in the traditions of "Ehricsen's disease," when it was believed to be due to spinal commotion. We now know that both spinal and cerebral commotion produce a clinical syndrome quite different from the traumatic neurosis. Concussion causes immediate symptoms, which may gradually pass off. In traumatic neuroses the symptoms rarely occur for some hours, days, or even weeks, and do not occur in all people; they require the predisposing cause, which in this case is the really efficient one. It is constituted by the suggestions of others, either already present in the patient's mind more or less consciously, or presented to him at the time of or after the accident by the injudicious solicitations of relatives, friends, or very often by the doctor who still believes in the anachronism of spinal commotion or traumatic neurosis.

The springing into consciousness of a latent suggestion by a shock is illustrated by the following

case: A girl was brought to Babinski having become monoplegic upon receiving an electric shock while crossing a tramway line.[9] This seemed like paralysis not caused by suggestion; but after the symptom had been removed by persuasion, further inquiry elicited the fact that the patient had overheard some months previously a conversation between some electricians who were speaking of the dangers arising from electric shocks of the above description. It is evident that upon experiencing the shock, there had flashed into the patient's mind a datum learnt from the conversation she had overheard and apparently forgotten; and that this memory furnished the suggestion at the base of the palsy she developed.

It is, however, not the shock itself which must be implicated here, but the ideational complex which it served to arouse. Complexes are the components of our mental life.[10] Any of the numerous branches may recall by association the whole complex, and thus the complex may then dominate the consciousness to the complete exclusion of all other ideas. The fixed idea is too common to need illustration. Now, the emotional mood is more or less *en rapport* with a person's intellectual content. Hence an idea connoting sadness is accompanid not only with the feeling of sadness, but with the physical reactions of that state, too. Normally any idea-emotion complex occupies the field of consciousness only until displaced by some other, as required by the exigencies of social adjustment. But when accompanied by powerful feeling-tone, a complex may remain or recur until that feeling-tone is satisfied dynamically, or replaced by another. A pecuniary solatium may furnish the dynamic satisfaction of the feeling-tone of injuries in traumatic neuroses.

This, however, is not the only means of doing so; for even the indemnity acts only in virtue of its effect upon the patient's *amour propre,* which may be flattered in many other ways, as by sympathy, understanding, etc., as is illustrated by the following case: A railroad brakeman was thrown by the giving way of a stirrup while his train was traveling about ten miles an hour. He fell on the small of his back against a bank of earth, rolled over two or three times, and lost consciousness for over half an hour. After crawling about half a mile he was found. He felt sick all over, and brought up blood, which also came from the bladder and bowels, only that day, however. After reaching his home town, he was assisted to his house, one and a quarter miles away. He did not sleep that night, but rested the next morning. In the afternoon he became restless, and sticking pains occurred in the back, and lasted several days. He was up and about with a crutch in fourteen days, but shortly afterwards he lost the use of his legs, having to move them with his hands, but he walked about on crutches, though he felt faint after progressing two or three squares. On account of anxiety and want of means he soon after went to live with his mother, his wife going to her father. When questioned, he replied, "Well, yes, I missed her"; but he stated that he was too much preoccupied with his health to care much. About three months later he was able to hobble with a stick only, but varied from day to day in his power to do so.

He said he felt a buzzing and a severe pain in the head as well as in the back; these did not begin until one month after the injury. He worried much over his position and circumstances, and the dependence of his wife, and in being unable to help her and his mother, who was an invalid with a younger boy to take care of. (He wept while relating this). He he never worried before his accident, but now he could not help it; for though he was owed $225 by an accident insurance company, they would not pay him anything. He did not know what to think about his health; for though the railroad doctor upon seeing him after the accident declared that he would soon recover and be able to work, he had lost over twenty pounds in weight, had become very weak, had sore throat and capricious appetite and sallow skin, and wept nearly every day. Moreover, about ten days after the injury, two other doctors, called in by his family, each said independently of the other that he had a congestion of the spine, which, though probably temporary, might last a lifetime. He had a very severe "fainting spell" one day after a cold; but when interrogated, he confessed to having eaten a large meal of sweet milk and cold slaw, and this was the only occasion since the accident upon which he had actually vomited, though he had often had a dull, sick feeling when overheated. He wished he had never seen a railroad, "meaning nothing detrimental to anyone but myself."

He had employed attorneys who were bringing a claim against the company; he had asked for two thousand five hundred dollars and employment, and had received much sympathy from his friends. When asked his object in this, he replied: "I will be frank with you and all. I was looking forward to promotion. It was no fault of mine that I was injured; if it had been, I would have said nothing. I merely ask for a sum of money and a job I could do. I could get around and do a job I could do, but I would never run railroad again; for in catching a box local, it means heavy weights all day, and I cannot gain promotion except through this." He thought he might do office work, though he dreaded it; for outdoor work suited him better than the confinement of bookkeeping; besides, a good brakeman could make a hundred dollars a month.

Upon examination, I found the tendon reflexes equal on the two sides and neither exaggerated nor unduly feeble. The cutaneous reflexes were all unusually active with the exception of the plantar, in which, however, the toes distinctly flexed upon several occasions, until inhibited volitionally. When I distracted his attention, flexation again occurred. Sensibility: A pin prick on the lower limbs is called a punch; cold steel is called warm, and the diapason is felt only when in full vibration. Cotton wool is unfelt in front as high as the groin, and behind as high as the iliac crest on the right side, at first; but after the left side had been examined and found insensitive only as far as the gluteal fold, he confessed to feeling the wool on the right buttock also. When asked to say when he did not feel the wool, he said "no" the first seven times he was touched on various parts of the lower limb, later ceasing to reply. The gluteal esthetic boundary varied by about two inches at different examinations. In the lumbar region, he was bilaterally hyperesthetic in a two-inch zone, shading off below and sometimes extending onto the buttocks. Posteriorly, the upper border of the zone corresponded to D. 12 and L. 1; laterally to D. 10-11, and anteriorly to D. 8-9.

The motor power was good. When he attempted to use the legs alone, he strongly tightened up the antagonistic muscles; but when his attention was diverted he could maintain powerful extension at

the knee, even on the left side, though he declared himself weak there from an old dog-bite. Babinski's combined flexion, and Hoover's and Zenner's tests were all negative. The pupils are equally dilated, and respond promptly and vigorously to light and accommodation, but no pain reflex could be elicited. There was no loss of memory or other intellectual defect, although the affectivity was perturbed as described.

It should be evident that the incapacity of this man arose from the fixed idea, very probably inculcated after the accident by his friends, although contributed to largely by the common belief of railroad employees, that an accident can induce serious nervous disease. The doubtful prognosis of the doctors, evidently unskilled in neurological diagnosis, strongly fortified the man's belief and consequent anxiety. The anesthesia, produced by previous medical examination, might have deceived an inexperienced observer; but the wool test, which had not previously been employed as I performed it,[11] quickly revealed not only an "uneducated" line of demarcation, but demonstrated that the man did feel by the very fact that he said he did not. Of course, even had I not succeeded in thus demonstrating the incongruity of the syndrome with the neuropathology of the spinal cord, the complete conservation of all the reflexes was sufficient to show that the anesthesia did not arise from disease of the spinal cord.

The diagnosis, then, was hysteria, the psychic elements of which were clearly revealed in the foregoing history. The prognosis given was favorable; but I first explained to the patient and doctor separately the real genesis of the disorder, showing the former the effects of worry and anxiety upon bodily nutrition and the rôle of ideas over bodily activity.

The treatment I recommended was the reestablishment of good nutrition, regular exercise, a removal of grief and worry by the assurance of a reasonable compensation for the anxiety and loss he had suffered (for though his ideas were erroneous, and he was in one sense of the word a simulator, he was so unconsciously, and because of the environmental beliefs he had acquired), and the declaration that by following my treatment he would be capable of moderate work in a few weeks, and in a short time would be entirely restored to health. Being asked for a certificate, I gave the following to both patient and doctor: "This is to certify that I find Mr. V. to be suffering from a condition of incapacity for free walking or mental or physical work from the effects of a fall from a brake car (as I am informed.) This state is induced, as a result of the aforesaid accident, by the worry, anxiety, and loss of means directly caused thereby. I believe that by appropriate treatment he could be restored to a certain extent within one month; and that within three months he could be fully capable of pursuing any laborious avocation he chose. He is, however, at present in too low a state to be capable of long, continuous labor, even though the incapacity of his limbs were immediately removed. There is, and has been, no disease of the spinal cord or peripheral nerves at play in the induction of any of the symptoms which I find. The erroneous belief that there has been such an injury powerfully contributes to the anxiety which maintains his present state."

As to the outcome, a letter from the doctor a few days ago stated in reply to my query: "We compensated V. by a sum of six hundred dollars; and he went back to work *on time* just as you predicted." *Naturam morborum curationes ostendunt.*

It is true that during shock or other emotion, intellectual control may decrease, and suggestibility be favored. Thus, Sir Arthur Mitchell[12] has demonstrated that during blushing and laughing as well as in dreams the conative element of our psychic life is in abeyance, and one is practically insane for the moment, self-control being gone. A parallel case is that of fright; but this still quickly passes away unless maintained artificially ideationally from a suggestion, not necessarily made after the event, but perhaps latent, as in the case previously reported. The suggestion need not even be explicit; but often is implicit in the whole conduct of those who surround us, and may be made by manifestly insincere attempts to minimize what it is easy to see is believed to be a grave danger. Every animal trainer knows how contagious is alarm; and similarly among primitive intelligences, suggestions of fear are quickly seized. Guy de Maupassant and Zola have vividly depicted the genesis of fear by this mechanism. But, as I insist, these states quickly pass unless they have some powerful ideational basis for their maintenance.

The evidence adduced to prove that a so-called visceral or vasomotor neurosis due to a physiological path[13] acquired in the spinal and lower neuroses is very meager. (The word *neurosis* is used by these writers in a very different sense from that given by Souques,[14] when he describes what really is a neurosis; Sherrington[15] justly employs the term psychosis to signify telencephalic reactions.) The disposition toward precurrent and consummatory reflexes organized phylogenically as instincts inheres in the neuronic arrangements very differently to the labile differentiability of psychic adaptation in the neopallium. It is to the latter that we must look in explaining the reactions of these patients; and that these are mental, not neuronic, is shown by their ready modifiability by mental means.

It is thus again to "idea" that we must resort in order to explain the perpetuation of even the motivity of this psychoneurosis. Moreover, it is a question of a notion dominating because it is unmodified by other, correcting or inhibitory ideas, *i.e.* it is a suggestion.[16] Hence, of traumatic neuroses suggestion is the sufficient cause, and none of the others alleged is even essential. The traumatic neurosis is therefore pure, unadulterated hysteria, for its primary symptoms are each "susceptible of production by suggestion and of disappearance by means of suggestion-persuasion."[7]

As to the diagnosis of susceptibility, it may be affirmed, and not merely guessed; for the method of exclusion need no longer be relied upon when differentiating psychic disorders.[17] Thesigns by which we distinguish psychic symptoms are as positive, clear, and demonstrable as any other reaction observed at the bedside.[18] For instance, a blush induced by a suggestion by the investigator is as much an observable, unmistakable, pathognomonic reaction as is the more simple extensor reaction of the great toe when the sole of the foot is lightly stroked in a patient having a disorder of the motor projection fibers in the pyramidal tract or elsewhere in their course.

The tests we employ for the estimation of attention, perception, memory, association of ideas, fatiguability,[19] differ not in kind, but only in complexity from those employed in the mensuration of motility and sensibility, including the function of the

special senses, the validity of which is disputed by no one. Even the emotions are now being studied by the exceedingly delicate galvanometric method of Féré,[20] resuscitated by Tarchanoff,[21] Veraguth,[22] and employed by Jung,[23] Petersen,[24] Sidis,[25] etc.

We are not in a position to measure the very complex reaction known as suggestibility; but it would be as absurd on this ground to forbid us to ascertain it clinically as would be the prohibition of cardiac murmurs as physical signs unless we measured their sonority instrumentally. Just as skill in an appreciation of cardiac murmurs requires a long apprenticeship in auscultation, much more does the technique for the elicitation of suggestibility require training and experience.

The outstanding corollary of these doctrines is the tremendous power of the medical attendant to impose, or not, upon his patient an idea which may create such a derivative of the imagination as a syphilophobia, astasia-abasia, a paralysis or weakness of an extremity, or any of the numerous imaginary diseases suggested by medical men by injudicious questioning or advice.[6] I need not here discuss the deliberate venality which arouses fear for its own profit; for that fear is often allayed by the ingenuity by which it has been incited. I speak only of the blunderer in whose mind the idea of organic disease permeates his conduct so as to alarm the patient. Nor need I do more than allude to a factor which has led to much confusion, viz., simulation; for it has been most luminously analyzed with rare psychological insight by Dupre.[26]

A false and exaggerated optimism is in this respect as fertile in unfortunate suggestions as is the preceding method; for the patient quickly perceives the insincerity of his attendant's remarks. Both attitudes arise from the want of precision in methods, and consequent uncertainty of diagnosis.

To the doctor's temporizing thus engendered we must attribute the birth of evolution of the so-called traumatic neurosis. Now, pathology has taught us that spinal and cerebral commotion cannot give rise to symptoms of the character and duration complained of by the victims of railway spine, and that hematomyelia and concussion are both very different clinical pictures. Chemistry has taught us that no constant change occurs in the secretions of these patients. From biology we learn that other organisms suffer from just such disabilities independent of trauma; and from ethnology that other races and peoples show a similar syndrome, though the thought of a railway train has never entered their heads. Psychology has taught us that such symptoms can arise purely from an idea, and can be removed by another idea.

We cannot then attribute this disease to trauma as such, but must do so to the expectation of medical men of the last generation that such a condition was biologically present, and to the consequent present belief in its existence by the laity, who are always laggards in science.

This popular belief is prevented from dying by the few medical men who still foster the doctrine that trauma can itself produce the neurosis in question. Whether it is done through respect for authority, by following the fashion, on account of want of information, or by reason of venality, the effect on the public mind is alike; and it is high time that we, as a profession, orientated ourselves as regards hysteria in a fashion at once precise and comprehensible, so that an end may be put to the scandal of permitting a premium to be placed through our fault upon want of hardiness, lack of self-respect, forgetfulness of obligations, even when simulation, unconscious or deliberate, is not in question.

To do this the first essential is a thorough knowledge of the organic nervous diseases, revealed by our studies in clinical neurology, and the second requisite is due, not exaggerated, appreciation of the rôle of the psyche in the production of symptoms apparently somatic.

When psychological mystification is replaced by diagnostic positiveness, such results as were shown by my own and Bevan's cases are more likely to be the rule than the exception, as at present. Only in this way will disappear the reproaches suffered by our profession for incompetence in the face of certain long-standing nervous affections of which the functional nature is later proved by a cure through Christian Science, Mental Healing, and other faith cures. Sometimes, the psychic element in the recovery is not so clear; for example, when it is disguised in such procedures as cheiropraxy, osteopathy, homeopathy, or even in some cases electrotherapy when indiscriminately applied. Any of these means, just as surely as drugs, may affect a symptomatic cure merely through the suggestion they convey. In this respect it is to be regretted that the procedure of too many practitioners is defective; for many, when uncertain or vague in their diagnosis, will run the gamut of their armamentarium on the chance of a lucky hit. Even the therapeutic blunderbuss is by no means extinct.[27]

It is to be feared that even the careful studies of the adherents of the psychoanalytic method need revision regarding the suggestions unconsciously made by the observers.[28] Until this is done this field, promising though it may appear, must be entered with due scepticism.

THE FIRST AMERICAN HOSPITAL.*

By JAMES J. WALSH, M.D., Ph.D., LL.D.,

NEW YORK.

DEAN AND PROFESSOR OF NERVOUS DISEASES AND OF THE HISTORY OF MEDICINE AT FORDHAM UNIVERSITY SCHOOL OF MEDICINE, NEW YORK.

Medical friends who were very much interested in my sketch of The First American Medical School (*New York Medical Journal,* October 10, 1908), and who were surprised to learn that the first medical school in America had not been founded within the limits of the United States, but that the University of Pennsylvania School of Medicine which we have been accustomed to think of as the first one was anticipated by nearly two centuries by the Medical School of the University of Mexico, have wondered how any serious medical teaching could be done without a good hospital and have asked about the first hospital in America. Like the first medical school, the first hospital in America was founded in the City of Mexico now nearly four centuries ago, and it is still in existence. It was used for purposes of clinical teaching over three centuries and a half ago, and is a standing lesson of how much sooner the Spanish-Americans seriously took up the solution of social problems than the English-Americans.

The whole subject of early Spanish-American development and progress, but especially of Spanish-American education, has in recent years been attracting profound attention in this country. As a consequence there has come a knowledge of the realities of the history of education in this country that has quite revolutionized certain older ideas. Professor Bourne of Yale, in the third volume of the American Nation Series, does not hesitate to declare that "It is not too much to say that the institutions of learning founded in Mexico in the sixteenth century, in number, range of studies, and standard of attainments by the officers surpassed anything existing in English-America until the nineteenth century. Mexican scholars made distinguished achievements in *some branches of science, particularly medicine and surgery,* but preeminently linguistics, history and anthropology." As a distinguished professor of medicine in this country said not long since: "It is indeed a surprise to find that while we have been accustomed to think of the Anglo-Saxon as the prime mover in education in this country, he was long anticipated in this by the Spanish-American, though we have been rather accustomed to despise the Spaniard for his supposed neglected education."

The first universities in this country were founded by a decree of the Spanish King in 1551. They were organized in the course of the next two years, though at first only the undergraduate and the theological departments took students. In the course of the first decade, however, law schools had been organized in both the University of Lima and the University of Mexico, and before the end of the sixteenth century both of them had medical schools. During the seventeenth century the number of students at the University of Lima rose to 2,000, according to Professor Bourne of Yale, and there were probably 1,500 at the University of Mexico. Both universities were fully organized universities in which the departments of theology, law and medicine were open only to graduate students. A man had to have taken at least three years of university undergraduate work before he was allowed to enter these departments. When we recall the unfortunate state of affairs which in the United States separated these graduate departments from the universities to the serious detriment of all of them, the work of the Spaniards becomes all the more interesting.

It is not surprising that the people who took such good care of the organization of education should have very early founded hospitals. It is rather astonishing, however, to find that the first hospital still exists and, above all, to learn from the description and pictures of it what a handsome structure it was. This first American hospital, still in existence, was built by Cortez, the Conqueror of Mexico, before 1524. The site chosen for it was that whereon Cortes and his followers first met Montezuma and his Mexicans. Cortez seemed to have had some qualms of conscience as to his treatment of the natives. He feared that he would be held to responsibility for it, and so he obtained a grant of this land from the Emperor Charles V, and erected on it a hospital which he endowed out of the revenues obtained from the property conferred upon him by the Spanish Crown for his conquest of the Mexicans. The hospital was originally called by his desire the Immaculate Conception. In the church adjoining the hospital, however, there was a shrine with a famous image of Christ, called Jesus Nazareno. Because of the fame of this, both church and hospital came to be called by this title, so that this first Mexican hospital is now known as the hospital of Jesus.

Cortez declared in his will that he had established and endowed the hospital "in recognition of the graces and mercies that God had bestowed upon him in his discovery and conquest of New Spain and as an expiation or satisfaction for his sins, and especially for any of his faults that he might have forgotten, but might still be a burden on his conscience, though owing to his forgetfulness he could not make a special atonement for them." Perhaps the most interesting thing about the hospital is the fact that Cortez so arranged the endowment for it that it has continued to be paid down to the present day. It was never given over to the State, but is a special corporation under a superintendent, and so it has survived the changes of government and the revolutions in Mexico. Cortez' principal descendants are the Italian Dukes of Terranova é Montaleone, and they have still the right to name an agent to supervise the hospital. This they do regularly so that the institution has been kept to its original intention and usefulness. The whole foundation from the beautiful building, the finest of its kind on the continent, to the method of the management of the endowment, appeals to this generation of ours which is trying to accomplish just such results as Cortez, by due consideration, found it possible to secure in the first quarter of the sixteenth century.

Strictly speaking, even this was not the first hospital in America, though it is the first one of which

*A communication presented at a preliminary meeting of the Guild of St. Luke, New York City, June 23, 1909.

we have any very definite records, and of course, its existence at the present day gives added interest to it. Prescott in his History of Mexico refers to Torquamada's Monarquia Indiana as authority for the statement that there were hospitals in all the larger cities of Mexico before the coming of the Spaniards and that there was a magnificent hospital organization. Hubert Howe Bancroft in his "Native Races of the Pacific States of North America," says that among the Mexicans "for severe cases the expense of treating which could not be borne except by the wealthy classes, hospitals were established by the government in all the larger cities of the native states of Mexico before the coming of the Spaniards, and experienced doctors, surgeons and nurses well versed in all the native healing arts were provided for them." There was even clinical teaching in these hospitals, and as it was the custom for the profession of healing to descend from father to son the opportunities for a good training in medicine and surgery will be appreciated. Women occupied positions in these hospitals not alone as nurses but also as physicians, and women's diseases and obstetrics were entirely in their hands.

Some of the first books written by the Spanish physicians, and especially the professors in the Mexican medical school, were with regard to this old-time Indian medicine. There seems to have been much more of medicine known to the Indians everywhere than we are likely to think possible. Dr. Chanfa, who had been physician-in-ordinary to the King and Queen of Spain, and who joined the second expedition of Columbus, apparently still under salary from the Spanish Crown, as a scientific attaché, wrote a volume of scientific observations on the voyage, in which he dwells particularly on the medicine of the Indians, their knowledge of simples, and their habits and customs with regard to the sick, besides giving much information with regard to the botany, zoology and meteorology of the regions visited. A brief compendium of this volume was published a few years ago by Dr. Ybarra of New York in the *Journal of the American Medical Association*, and in the Smithsonian publications.

Those who are surprised that Cortez' Mexican hospital of the first quarter of the sixteenth century was so fine a building need to recall the earlier tradition of native hospitals, and also the state of hospital construction throughout the world at that time. Cortez' hospital seems to have had some of the features of the famous hospital built by the Visconti in Milan. This is probably one of the handsomest hospital structures in the world. One of the arcaded courtyards which is the subject of endless admiration, was built early in the sixteenth century, shortly before the time when this Mexican hospital was erected, and the plans for it are said to have been made by Michael Angelo. In certain ways the Ospedale degli Innocenti at Florence, which was more a foundling asylum than a hospital in our modern sense, is also another striking example of the beautiful hospitals of the early period. The Hospital of Siena should also be cited in this list, for it confirms the idea that men were deeply occupied with the thought of making their public hospitals as beautiful as possible, as well as useful. We have only come back in recent years to the idea that public institutions for the poor must uphold the dignity of the municipality, and though they are to harbor the poorest of the citizens, must carry no hint of poverty, but must represent the beneficent expression of the city's feelings toward its citizens.

The Mexican hospital, with its arcades and courtyard, is built after the model of many of the hospitals of Europe erected in the preceding centuries. Some of the finest hospitals in the world were planned and built during the thirteenth, fourteenth and fifteenth centuries. There is a hospital at Tanierre, in France, erected about the beginning of the fourteenth century, that is a model of its kind. Many of the features of it show how earnestly these people of the old time had studied the problems of hospital construction. In describing this hospital at Tanierre, Mr. Arthur Dillon, a New York architest, said:

"It was an admirable hospital in every way, and it is doubtful if we to-day surpass it. It was isolated, the ward was separated from the other buildings, it had the advantage we so often lose of being but one story high, and more space was given to each patient than we can now afford. The ventilation by the great windows and ventilators in the ceiling was excellent; it was cheerfully lighted, and the arrangement of the gallery shielded the patients from dazzling light and from draughts from the windows, and afforded an easy means of supervision, while the division by the roofless, low partitions isolated the sick and obviated the depression that comes from the sight of others in pain.

"It was, moreover, a great contrast to the cheerless white wards of to-day. The vaulted ceiling was very beautiful; the woodwork was richly carved, and the great windows over the altars were filled with colored glass. Altogether, it was one of the best examples of the best period of Gothic architecture."

This tradition of building fine hospitals continued in Europe until the beginning of the sixteenth century. The first American hospital, as erected in Mexico, was due to a direct continuation of this old tradition carried over by the Spaniards from the mother country where, during the preceding century, some magnificent hospitals had been erected. Unfortunately an end of the great hospital movement of the Middle Ages was reached just at this time, and the development that had been secured in hospital organization did not maintain itself. The history of hospitals for the next three centuries nearly everywhere throughout the world is a sad commentary on the supposed constant evolution of man from a lower to a higher state. Ordinarily it is supposed that succeeding generations improve on what their predecessors have done. With regard to hospitals, however, just exactly the opposite followed during several centuries after this.

During the century that followed the erection of Cortez' hospital in Mexico there came a period of very serious decadence. This has been very well expressed by Miss Nutting and Miss Dock in the chapter, "The Dark Period of Nursing," in their "History of Nursing." They said: "It is commonly agreed that the darkest known period in the history of nursing was that from the latter part of the seventeenth up to the middle of the nineteenth century. During this time the condition of the nursing art, the well being of the patient, and the status of the nurse all sank to an indescribable level of degradation." Jacobsohn says (Beiträge zur Geschichte des Krankencomforts, *Deutsche Krankenpflege Zeitung*, 1898), that "it is a remarkable fact that attention to the well-being of the sick, improvements in hospitals and institutions generally, and to details of nursing care, had a period of complete and lasting stagnation after the middle of the

seventeenth century, or from the close of the Thirty Years' War. Neither physicians nor officials took any interest in the elevation of nursing or in improving the conditions of hospitals. "During the first two-thirds of the eighteenth century," he proceeds to say, "nothing was done to bring either construction or nursing to a better state. Solely among the religious orders did nursing remain an interest and some remnants of technique survive. The result was that in this period the general level of nursing fell far below that of earlier periods. The hospitals of cities were like prisons, with bare, undecorated walls, and little dark rooms, small windows, where no sun could enter, and dismal wards where fifty or one hundred patients were crowded together, deprived of all comforts and even of necessaries. In the municipal and state institutions of this period the beautiful gardens, roomy halls and springs of water of the old cloister hospital of the Middle Ages were not heard of, still less the comforts of their friendly interiors."

This first American hospital then is interesting also as a landmark in the history of hospital construction and organization. It came at the end of a great period of hospital building during which all the necessities for hospital work had been carefully thought out and details of construction planned for the benefit of the ailing. After it all over the world a period of hospital decadence began which culminated at the end of the eighteenth century. Real improvement did not come until well on into the nineteenth century. The second American hospital was built at Santa Fe in Mexico, but was not as beautiful as the one in the capital, and is not now in existence. The next American hospitals came in Canada, but while the French gave some attention to humanitarian work, the French Government was not so liberal in its support of colonial institutions, charitable and educational, as was the Spanish Government. The Hotel Dieu in Quebec is on the same spot where the original Hotel Dieu was, but the first building has long since disappeared. It has a continuous history ever since, and Miss Nutting and Miss Dock in their history of nursing already referred to, tell the wonderfully human and interesting story of its foundation and early struggles for existence.

A NOTE ON THE STAINING OF BLOOD FILMS.*

By JESSIE WESTON FISHER, M.D.,

MIDDLETOWN, CONN.

Recognizing the desirability of an easy method for staining blood films, and that such a method needs to be rapid, easy of application and constant in its results, this slight modification of Jenner's stain is presented with the hope that it will fulfill these requirements and recall from oblivion an undeserved by neglected method. Of the original Jenner's stain, Simon[1] says, "For routine purposes I can recommend this stain without reserve."

The medical profession is coming to realize more and more the value of blood examinations in the diagnosis of disease. The stained smear is the simplest of the methods used in the study of the blood and the one which can the most readily be utilized by the busy practitioner, giving as it will a greater amount of information, if properly studied, than any other one blood examination.

*From the Laboratory of the Connecticut Hospital for the Insane.

Information Obtained from Stained Blood Smears.—A fair estimate of the percentage of hemoglobin can easily be formed by the intensity of the staining of the red cells. Alterations in their size and shape, together with nucleated forms, means pernicious anemia; stippled cells speak for lead poisoning; malarial parasities mean malaria; eosinophilia suggests trichiniasis; many myelocytes, myelogenous leukemia; lymphocytosis, lymphatic leukemia. Of course, the well known value of a differential count scarcely needs mention, and some knowledge can be obtained of the presence or absence of leucocytosis in an evenly spread blood film.

Stained blood smears are within the reach of every doctor owning a microscope, and every patient presenting fever, pallor, or obscure symptoms of any kind has a right to demand the benefit of such a simple examination, making it as much a matter of routine as the examination of the urine.

There are, unfortunately, almost as many different methods of staining blood films as there are laboratory workers, hence it is hard for the general practitioner to select a technic giving him the best results at a minimum expenditure of time and labor. Each operator, consciously or unconsciously, modifies a given technic to suit his needs, but no one ever seems to get exactly the same results as the originator of a certain method, due probably to minor and unconscious modifications which are practically impossible to describe on paper.

Peebles and Harlow[2] have claimed that the reaction of the stain is the important point and is due to changes in the methyl alcohol. They claim that an acid stain will not stain the neutrophilic granules and nuclei sufficiently. A solution too alkaline will stain nuclei and granules, but the red cells do not stain well.

Emery R. Hayhurst[3] gives an excellent method, but one which requires the use of two solutions and the exclusion of air from the staining films which necessarily complicates the technic. Jerome E. Cook[4] describes a stain which gives admirable results, but great care must be given to the technic.

Most of the methods in use seem to require too much manipulation, consumption of time, or attention, especially for the general practitioner. We have tried many methods in this laboratory, including eosin and methylene blue, Romanowsky's, Ehrlich's stain, Leishman's, Jenner's, Wright's, Hasting's, Harlow's, etc. The most uniform results have been obtained from a slight modification of Jenner's stain which requires the use of no other apparatus than the staining solution and slide, and is prepared after the following formula.

Preparation of the Stain.—Take 200 c.c. of a 1.25 per cent. solution of yellow aqueous eosin in distilled water and mix with 200 c.c. of a 1 per cent. solution of methylene blue, medicinally pure, Grübler, in distilled water. Any of the Grübler blues work satisfactorily. Allow this mixture to stand in an uncovered shallow porcelain evaporating dish for twenty-four to thirty-six hours protected from dust. At the end of that time, filter through a fine grained filter paper. The residue on the filter is dried in the incubator or oven at 55° to 60° C. This powder is shaken up with cold distilled water, filtered through fine paper, and washed with distilled water until the washings are a thin dirty purplish color. Dry the precipitate on the paper, either in the air or in the oven not above 60° C., then scrape off the powder and store in a bottle.

This gives enough powder for about 300 to 400 c.c. of stain. Any of the commercial houses could easily prepare this stain, thus making the actual office work trifling.

Preparation of Staining Fluid.—Take the above powder, 0.2 gram, and of methyl alcohol (acetone free), 100 c.c. Rub up in a mortar, adding the alcohol to the powder, a drop at a time, allow to stand for three or four days in a bottle, then filter and add 25 c.c. of methyl alcohol. The addition of the methyl alcohol is for the purpose of thoroughly dissolving all the stain and diluting it sufficiently. The bottle should be corked tightly to avoid evaporation and consequent concentration of the stain, but the solution may be diluted later with another 25 cc. of methyl alcohol if necessary. The solution is purplish blue in color and is without sediment or precipitate. The fluid is now ready for use and will keep indefinitely. We have kept some for years in a clear glass bottle on an open shelf in the laboratory.

We generally make blood films on slides, using another slide or cigarette paper for spreaders. Smears are dried quickly in the air, then covered with a thin layer of the staining solution without previous fixation. If too much solution is used, staining is not as rapid as when there is a thin layer of the stain. The stain is allowed to remain upon the slide one to three minutes, then it is washed with some of the original solution, removing any possible precipitation and intensifying the stain. Pure methyl alcohol used for this purpose decolorizes too rapidly. The slide is next washed in running water until the film is a mahogany color. Distilled water may be used if preferred, but there is no advantage in so doing. It is finally dried with filter paper and is now ready for examination. If by chance the staining solution is allowed to dry upon the film, no harm results as would be the case if other methods were used. In this case it is only necessary to apply a fresh solution to dissolve the dried stain and proceed as before. It is impossible to overstain. There is no danger of spoiling smears, thus necessitating another visit to the patient and consequent loss of valuable time.

Microscopical Appearance of Stained Blood Smears.—The red cells are stained a terra cotta; stippled cells are easily detected by the minute bluish markings; nuclei are blue and sharply defined; blood platelet in clumps are a paler blue but quite distinct; granules of the polymorphonuclears are a dull mahogany; granules of eosinophiles, a brighter mahogany; basophilic granules are bluish violet; malarial parasites are stained a greenish blue; the pigment of the pigmented forms is unaltered, and the ordinary bacteria are stained blue. This method of staining is used in counting bacteria for vaccines and the opsonic index.

If the reaction materially alters the action of the staining solution, this laboratory has been peculiarly fortunate in the constancy of this stain, for the last in the bottle always stained as well as the first. However, it would be well before making the solution to test the methyl alcohol; if acid, it could be neutralized by sodium carbonate before making up the stain. Merck's acetone free methyl alcohol seems to be constant in reaction and gives excellent results.

Summary.—This stain can be prepared by the commercial laboratory. It will keep indefinitely. Its application is simple, requiring only the blood film and staining fluid for its consummation. It will not overstain if left until dry. Its results are constant and can always be relied upon. It stains malarial parasites and bacteria.

STENOSIS OF THE VESICAL OUTLET FOLLOWING PROSTATECTOMY.*

By J. BENTLEY SQUIER, M.D.,

NEW YORK.

A SEARCH of the literature on prostatectomy shows but few reported cases of stenosis of the vesical outlet following operation. Some writers allude merely to the desirability of an occasional passage of a sound to guard against possible stricture of the deep urethra, and others regard this as an unnecessary precaution. Two such cases having come under my observation recently makes me feel that the subject is of more importance than has hitherto been considered, and therefore justifies this brief communication.

The first case of this character was a patient of Dr. L. Bolton Bangs. He has already reported this case in detail before the Medical Society of the State of New York, therefore I will only outline its most salient features. The patient was aged sixty-six and gave evidences of marked general sclerosis. Perineal prostatectomy was performed for, practically, total retention of urine, and the patient made a quick, uneventful recovery from the operation. At the end of eighteen days, when he left the sanatorium and returned to his home, he was voiding urine every four hours and completely emptying his bladder. A month later he began to develop increased frequency with dysuria. The stream had become dribbling and feeble. His physician found it impossible to catheterize him, and Dr. Bangs was called to his home in consultation. As I had assisted Dr. Bangs at the prostatectomy he invited me to be present at this consultation. We found it impossible to enter the bladder with any instrument, the obstruction being deep in the urethra. Suprapubic cystotomy was decided upon with the idea in view of retrograde catheterization. After the bladder was opened, the following conditions were found, the description of which I give in Dr. Bangs's graphic words: "Careful examination of the interior of the bladder, repeated both by myself and my associate, Dr. Squier, failed to find any normal internal meatus; but at the anatomical situation of the latter could be felt a shallow, funnel-shaped dimple. Inferior to this was a thickened bladder which, aided by bimanual palpation with two fingers of the other hand in the rectum, was made out to be the contracted capsule of the prostate covered by the muscular and mucous wall of the bladder. All efforts to introduce instruments of minute size into this dimple failed. Consequently, a staff was placed in the urethra and the perineum freely opened. Short, thick, interlacing fibrous bands had displaced the normal structures, and although there was a series of shallow pockets between these bands,

*Read before the American Association of Genito-Urinary Surgeons, May 31, 1909, at Mount Pocono, Pennsylvania.

forming a semblance to an irregular channel, no opening leading from this channel into the bladder could be found. A blunt-pointed instrument was then placed in the conical dimple within the bladder, and being held firmly in place by my associate, I severed the bands in the perineum until the point of the instrument was reached and an opening thus made into the bladder through which the index finger could be introduced. A sound of the size of 26 F. was then easily passed from the meatus into the bladder. Suprapubic and perineal drainage were established, which the patient bore very comfortably and convalescence from this second operation was uneventful."

The second case occurred in my service at the New York City Home. The patient was sixty-nine years of age. His urinary history dated back to November, 1906, when a benign tumor was removed from his bladder by suprapubic incision at the Metropolitan Hospital in New York City. On June 9, 1908, at a second New York City hospital, he was given suprapubic drainage of the bladder for the relief of retention of urine. He left this hospital before the wound had healed and was lost sight of until October, 1908, when he appeared at another New York City Hospital and a suprapubic prostatectomy was performed by a surgeon well skilled in such work. Following this operation a ventral hernia developed, and three months later he went under a secondary operation for repair of the rupture. He came under my care on February 9, 1909, when he was suffering from dribbling of urine, tenesmus, dysuria, and abdominal pain. I found on examination a bladder distended almost to the ensiform cartilage and the patient's general condition was very grave. Repeated attempts to enter the bladder by way of the urethra demonstrated an impassable obstruction to the entrance of any instrument, even a filiform bougie. Suprapubic cystotomy was at once performed under local anesthesia, and a condition was found similar to that in the case previously related. The situation of the internal meatus was located by a dimple in the center of which was an opening through which it was barely possible to pass the finest filiform. This opening was enlarged by making stellate incisions through a dense cicatrix which had formed around the vesical neck at this point. A sound No. 30 F. was passed through the penile urethra into the bladder after I had demonstrated by the bougie à boule that there was no stricture formation at any other point in the urethra. The bladder was drained only suprapubically. The consequent course of the convalescence was uneventful. A sound was passed every three days for three weeks. The suprapubic wound healed kindly, and now, three months after operation, the patient empties his bladder completely and the occasional passage of a sound has kept the urethra patent.

These two cases demonstrate that cicatricial stenosis of the vesical outlet may occur after either perineal or suprapubic operation. The prostatectomy in each instance had been performed by a surgeon with wide knowledge of the surgery of this region, and therefore the element of error in technic can be practically eliminated.

Possibly the complete removal of the prostatic urethra at time of operation may be responsible for the condition described, but as so many cases have been reported in which such removal apparently had no dire after-effects, this supposition is theoretical. It may be important to note that the cicatrix following the perineal operation extended along the site of the prostatic urethra for some distance, whereas the cicatrix resulting from the suprapubic operation formed only an essential collar around the vesical outlet, and did not appreciably invade the deep urethra.

Electricity in the Diagnosis and Treatment of Infantile Paralysis.—H. Marques divides the treatment of infantile paralysis and its symptoms into three stages. The first is the acute stage, when measures to lessen irritation and infection are in order. Next comes a stage of regression and paralysis. Beginning from the early days of the disease, paralysis is marked, and the muscles degenerate and atrophy. The electrical applications are now of great value in two ways: in diagnosis of the possibility of recovery in the paralyzed muscles, and for treatment of these muscles to keep up their tone until the greatest possible amount of repair has occurred in the spinal cord. The Faradic reaction is entirely absent from early in the disease in the paralyzed muscles, and the reaction of degeneration is shown by applications of galvanism to these muscles. Upon the character of the degeneration reaction depends the prognosis for recovery of the various muscles. The use of galvanism is invaluable; in fact, is the only means of treatment of any value in exercising the muscles and preventing atrophy. It is given at first in continuous application, followed by an interrupted current, the pole being used over the muscles that give the best contraction. The sittings should be short and only the amount of current strength that is needed to cause contraction should be used. The final stage of the disease is that of deformity. All possible repair has already taken place, and the time has come for keeping the joints in position by braces, to prevent changes in the joint structures, and for transplanting by surgical measures healthy muscles onto paralyzed tendons. The use of electricity to facilitate the action of the transplanted muscles, in cases of this nature, is of great value.—*Annales de Médecine et de Chirurgie Infantiles.*

Infantile Paralysis of the Muscles of the Foot.—Ch. Ducroquet and Paul Launay describe the operation of partial arthrodesis, devised by them to obviate the false position of the foot created by attempts to replace the paralyzed muscle by grafting onto the tendons slips of healthy muscles. It is impossible to tell how much effect the new muscle is going to have on the articulations of the foot. The great difficulty is that often the foot is thrown into the position of valgus or varus, and the sole of the foot cannot be placed firmly upon the ground in walking. The movements of the ankle joint that are most important are flexion and extension. The rotatory movements of the foot are less important and can be suppressed without great loss of function. The authors propose to suppress these movements in the calcaneo-astragaloid and mediotarsal joints and allow only extension and flexion. To this end they open these articulations and remove the articular surfaces of the cartilage, and cause ankylosis of these joints. They give the histories of such cases operated on with excellent results, and minutely describe the operation. —*La Presse Médicale.*

The Exudative Diathesis.—Claudio Ventura denotes by the name of exudative diathesis a condition obtaining in infants under two years of age, consisting of a transitory and repeated congestion, and turgescence of the skin and mucous membranes throughout the body. The special characteristic of this congestion is its evanescence. It occurs in children of debilitated parents, those that are of advanced age, and those that have debilitating diseases. There are congestions of the nasal and pharyngeal mucous membranes causing stopping of the nose and enlargement of the tonsils, that disappear rapidly; asthmatic dyspnea, and eruptions on the skin that simulate true eczema, urticaria, milk crusts, etc. The vesical, palpebral, and intestinal mocosa may be affected, and the liver is enlarged. After a number of such attacks a permanent hypertrophy of tissues may result. Geographic tongue without loss of appetite or bad general health are manifestations of this state. The cause of these attacks of congestion is a too large amount of the fatty constituents in the diet, and the treatment consists in reducing the diet to the smallest possible amount consistent with the preservation of life, leaving out the materials that will produce fats. No medicinal treatment, Ventura says, is of curative value, and it should be resorted to only as a palliative to the local manifestations.—*Rivista di Clinica Pediatrica.*

THE CAMPAIGN AGAINST YELLOW FEVER IN RIO.

For many years Rio de Janeiro was a close rival of Havana for the dubious honor of being the chief yellow fever center in the world, and for the last third of the nineteenth century it was easily in the lead, notwithstanding the armies of nonimmunes that Spain was constantly sending to Havana. In 1901, the year that Havana, for the first time in one hundred and forty years, had several months with no yellow fever mortality, Rio de Janeiro recorded 2,299 deaths and in the two years following had 1,568 deaths. Then the city awoke to its disgrace and the Public Health Service instituted a campaign under the able direction of Carneiro de Mendonça, who died while the struggle was most severe, but not until he had organized the Bureau of Yellow Fever Prophylaxis and had inspired his assistants with an enthusiasm which carried them on to victory after his death. Through the courtesy of the Department of Commerce and Labor we have received a copy of a report from the American Consul-General at Rio de Janeiro containing an authoritative and detailed statement of the means by which the sanitary regeneration of the city was effected. This is in the nature of a paper read by Dr. Oswaldo Cruz, chief of the Public Health Service of Brazil, before the Latin-American Medical Congress held in Rio de Janeiro, August 1 to 10.

The initiation of the campaign was beset with many difficulties, for although the health officials had the benefit of Gorgas's experience in Havana, the physical conditions in the two cities were very different. Rio de Janeiro is a city of nearly a million inhabitants, with 82,396 houses spread over an area of 430 square miles and of very irregular topography, the altitude varying from sea level to 1,600 feet. The workers had, of course, also to contend with the ignorant opposition of many of the inhabitants and were backed only by the civil authority which is never so implicitly obeyed as is the military. The campaign was begun the latter part of April, 1903, but it was not until January of the following year that a sufficient appropriation for the service was made by Congress. The army of yellow fever fighters consisted of 1 medical inspector, 10 sanitary inspectors (physicians), 1 administrator, 1 customs inspector, 1 accountant, 70 medical student assistants, 9 subchiefs, 200 overseers, 36 guards, and 1,000 laborers. With this force every house was visited, all water tanks and other places where mosquito larvæ might be found were inspected, the larvæ were destroyed, and further access of mosquitos was prevented. When a case of yellow fever was found the same routine was followed as that established in Havana, of screening the patient and destroying all mosquitos present in the house where he lived. All the persons in a district where yellow fever had occurred were kept under observation one month, during which time every inhabitant was inspected daily. In order to test the efficacy of the antimosquito measures employed, traps were set, from time to time, in the shape of uncovered vessels of water, which were examined at frequent intervals. In many cases no eggs or larvæ were found even after long exposure of the traps, proving the absence of mosquitos.

Owing to the difficulties mentioned, the results of this campaign were not immediately apparent, there being 289 deaths from yellow fever in 1905; but from that time there was a rapid fall, 42 deaths occurring in 1906, 39 in 1907, 4 in 1908, and none in 1909. The fever season in Rio de Janeiro corresponds, of course, to our winter, and as the 4 deaths in 1908 occurred early in the year, it follows that there were none during the hot months of 1908-9, so that Cruz appears to be justified in his claim that yellow fever in Rio de Janeiro has been wiped out.

This experience of the Brazilian health officials corroborates what events in Havana and Panama have demonstrated, that it is possible to exterminate mosquitos in a city, or at least to keep them within what Gorgas regards as the safe limit of numbers. The occurrence of an epidemic of yellow fever in any city of this country will therefore no longer be excusable on the ground of ignorance or of an unavoidable condition of unpreparedness. The authorities of a city who permitted combustibles to be stored in the open where a spark might start a devastating conflagration would be no more culpable than the health authorities who permitted the continuance of breeding places of the yellow fever mosquito, and the public will be not slow to place the blame where it belongs if any city in this country is ever again visited by an epidemic of yellow fever.

TUBERCULOSIS HOUSES.

In this century we are doing a great deal in the line of prevention and cure of tuberculosis, and we are accomplishing much, but there are important lines of prevention in which we have been able as yet to make but little headway, and it is very doubtful whether tuberculosis can ever come near to being stamped out until we are able to control in a sanitary way the abodes of the poor. An example of the near-sightedness of the municipality in this respect was failure of the endeavor made some years ago to have the so-called "lung block" razed and replaced by a beautiful, rest-giving park. Many of these rookeries cannot be made fit for residence

and should be demolished, since they are so infected with tuberculosis that no amount of disinfection can render them safe places of abode; others must have their dark rooms made light and well ventilated, and in this line much has been done in the borough of Manhattan by the Tenement House Commission, while much remains to be done in the other boroughs, where these evils exist although possibly in a lesser degree. Each one of them is a center from which the disease reaches out long arms to seize upon the dwellers in more sanitary houses. Another almost untouched source of infection lies in the sweat shops and factories where the tuberculous operative still sits side by side with his well neighbor, neither of them taking any precautions to prevent the communication of the disease from one to the other.

The reforms contemplated in this direction by another great and crowded city, Paris, are of interest. These as projected are described in the interesting reports made to the Prefect of the Department of the Seine for 1908 and 1909. In the first of these P. Juillerat gives an account of the investigations made by him since 1904 on the conditions present in the crowded districts of Paris, the results of which lead him to assert with emphasis that very many of these houses are hotbeds of infection. The height of the houses, shutting off the light, air, and sunshine from the narrow streets, the dark rooms, and unventilated places afford the conditions favorable to the continued existence of the tubercle bacilli which infect the new comer and the weakling. Should plenty of sunshine and fresh air be let into these places the plague could be stayed. Some of them are capable of improvement, while others can only be demolished. The question is how the city may gain authority to pull down these houses and substitute for them better ones. One of the greatest sources of infection is the furnished-room houses, where one family after another uses the same furniture, which, becoming infected, remains a source of infection for years. Families that use their own furniture are much less likely to have tuberculosis, according to the statistics obtained by the author. That the frequency of tuberculosis is in proportion to the height of the houses, and that tuberculosis is more frequent in the lower stories, are two facts that the author has observed. A house where deaths from tuberculosis are frequent is never found to stand alone; always the neigboring houses are struck by the white plague. The decisive struggle against this disease must be made by the municipality against the housing conditions of the city. The author recommended the appointment by the city of a commission to investigate further the conditions and to decide on the necessary legal measures. In 1909 the commission began its work and has made a partial report. It has been ascertained that in these centers of infection are many small factories in which artificial light only is used, and places where cooking, laundry work, and other occupations are carried on in basements. The people who inhabit these houses do so not from choice but from necessity. They must live near their work. The commission recommends the demolition of these houses and the erection of better ones in their places, with better light and air, with larger courts, wider streets, and frequent parks and breathing spaces, but at the same rents.

A careful inquiry was made into the living places of all patients at dispensaries, hospitals, and charitable institutions, with the result of confirming the data previously obtained regarding the unsanitary house. This investigation is still going on. Some of the immediate results are recommendations forbidding the use as habitations of 263 rooms now occupied, the modification of 873 rooms, forbidding the use of 91 rooms too small for use as habitations, modification of 43 small rooms, and many sanitary improvements of others.

Unusual Symptoms Due to Diphtheria Antitoxin.

Some French observers have recently reported certain interesting clinical facts connected with the use of antitoxin. Ever since the introduction of this substance, the occasional urticaria and joint pains due to horse serum have been well known. In the *Gazette Hebdomadaire des Sciences Médicales de Bordeaux*, Rocaz and Charles state that in laryngeal diphtheria, when the injections are made early enough and the patient is not too young, the evidences of laryngeal stenosis gradually disappear and the organ becomes normal; but occasionally a few days after the first injection an urticarial rash appears with a recrudescence of all the laryngeal symptoms, chest retraction, etc., in fact, all the symptoms of the primary invasion, suggesting a return of the exudate. This phenomenon was explained some years ago by Sevestrem and Martin, who maintained that the exanthem due to the serum was accompanied by an enanthem producing acute congestion and edema of the laryngeal membrane, which disappeared as the urticarial symptoms passed off. If intubation has been done and the tube removed its reintroduction may be necessary. Hence an intubation tube should not be removed when the serum rash appears. If, on the contrary, a tube has not been inserted, if the child has been doing well, the practitioner should not be in a hurry to insert one, since the threatening symptoms are only temporary. As reported in a recent issue of *The Lancet*, Rocaz and Charles give particulars of a series of cases of the following tenor: A boy, aged six years, was admitted into hospital on November 4, 1908, suffering from diphtheria with marked retraction of the chest and completely muffled cough. Twenty cubic centimeters of Roux's serum were injected and intubation was performed. On the 5th, 6th, and 7th the membrane persisted on the tonsils and the injection was repeated. On the 8th the membrane disappeared and the tube was removed. There was no retraction of the chest or dyspnea. In the afternoon an urticarial eruption appeared at 4 P.M., the retraction of the chest returned, and it increased more and more, in spite of the administration of a sedative draught. It was so intense at six o'clock that intubation was again necessary. On the 10th the eruption had disappeared and the tube was removed. In another case a boy, aged six years, was admitted on November 9 with intense retraction of the chest, but the condition was well borne and there was no cyanosis. Forty cubic centimeters of Roux's serum were injected. On the 10th the condition was unchanged and 20 cubic centi-

meters of serum were injected. On the 11th there was slight improvement, but the membrane persisted on the tonsils. Twenty cubic centimeters of serum were injected. On the 12th the retraction had disappeared but the voice was still muffled. On the 13th a serum eruption appeared and the retraction returned. On the morning of the 14th the retraction became as intense as on admission, but as it was well borne no operation was performed; sedatives were given, and the steam-kettle was used. Later in the day the whole body was covered with an urticarial eruption and the retraction was as intense as before. On the 15th the retraction and the eruption disappeared *pari passu*.

An Idiosyncrasy to Horse Serum.

Idiosyncrasies to certain odors have been reported with some frequency, the most common of them, next to the familiar hay fever, being probably that to the smell of the horse. Such cases have never attracted much attention, the most serious result being generally but a temporary coryza and the patient usually learning by himself that the only prophylaxis is the avoidance of the proximity of the horse. That such an idiosyncrasy may, however, cause dangerous symptoms is emphasized by an article in the *Berliner klinische Wochenschrift* for August 30, 1909. In this Arent de Besche reports a personal experience. As long as he could remember the author had been unable to drive behind a horse in an open carriage or to remain in a stable for more than a few minutes without experiencing an attack closely resembling hay fever. This applied to the odor of horses only, cows and donkeys not affecting him. Until he was thirty years of age this peculiarity was nothing more than distinctly disagreeable. At that age, however, it came near costing him his life. While in perfectly good health he was exposed to diphtheria, and as a result, for the first time in his life, submitted to an injection of 1,000 units of antitoxin in 2 c.c. of horse serum. Five minutes later he was affected with marked itching in the nose, running from the eyes, and almost incessant sneezing. He then began to cough and within ten minutes became markedly dyspneic and cyanotic, the attack resembling severe asthma. He felt weak and ill, had a chill, and his legs and arms were cold. His pulse was not palpable. He remained critically ill for two hours, after which the condition cleared up so rapidly that five hours from the onset the patient felt quite himself again. A point of considerable interest in this case is that this acute attack brought on by the horse serum produced a definite immunity in the patient to the milder type of attack from which he had suffered previously when exposed to the odor of horses. This lasted for three months, during which time he was able to drive behind horses or remain for long periods in stables with perfect comfort. At the end of that period the immunity gradually disappeared and the susceptibility to the odors returned. This case is of importance as showing a danger in the use of antitoxic horse serum, and suggesting the care with which it must be administered to those who suffer from idiosyncrasies to the odor of the horse.

Antituberculosis Leagues Among the Negroes.

The excellent antituberculosis work among the colored people of the South, inaugurated by Surgeon Wertenbaker of the Public Health and Marine-Hospital Service, of which we gave an account in a recent issue (Medical Record, August 14, 1909), is being continued and extended and gives promise of effecting great good. It is not only in helping the consumptive that good will be accomplished, but if the organization is successful in carrying out the work that has been outlined it should effect a hygienic regeneration of the negro which all the efforts of philanthropists in forty years have failed to accomplish. The proposed plan of organization contemplated the establishment of a State league having among its officers a vice-president in every county whose duty it would be to organize a branch league in every colored church in his county. It was soon found, however, that after such leagues were formed there was more or less difficulty in getting to work in an effective way since the organizers had had no previous experience. To remedy this, and to aid the county vice-presidents and the officers of the branch church leagues in the new undertaking, Dr. Wertenbaker has drawn up a working plan giving in all necessary detail the method of organization of these leagues, both State and branch. This plan was published in the Public Health Reports of September 3, 1909, and has now been reprinted in pamphlet form for distribution to those interested in the work. Requests for copies should be addressed to the Surgeon-General, Public Health and Marine-Hospital Service, Washington, D. C.

A Conference on Pellagra.

The sudden appearance of this disease in the United States is rather mysterious, or would be were it not explicable on the assumption that it is a sudden recognition rather than appearance. It may also be explained on the theory of contagion in which case it would be necessary to abandon the belief in damaged corn as an etiological factor. What the cause is, and indeed what the exact nature of the disease is, will not improbably be a subject of study and dispute for some time. Beriberi, a similar disease, has been studied for many years and it is even yet undecided whether it is caused by the eating of damaged or improperly cured rice or is a bacterial disease. But the sooner a systematic study of the malady is begun the sooner may we hope to discover the means of its prevention; and indeed no time should be lost, for in the few years that it has been recognized in this country it has already been found to exist in seventeen States. The State Board of Health of South Carolina is awake to the danger which threatens the country from this source, and through its secretary, Dr. C. F. Williams of Columbia, S. C., has issued an invitation for a National Conference on the subject, to be held in Columbia on November 3 and 4. The call which the Board has issued extends an invitation to physicians and sanitarians throughout the country to attend the conference. The program of the meeting will include not only addresses, papers, and discussions, but a number of clinical cases will be presented, thus affording an excellent opportunity for the study of the disease. The subject of the treatment of pellagra is discussed by Dr. C. H. Lavinder, of the Public Health and Marine Hospital Service, in "Public Health Reports" of September 10. He says that arsenic is the remedy which has thus far given the best results in the treatment, but the success has not been great, and it is evident that a further study of the etiological factors is necessary as a preliminary to any satisfactory method of prophylaxis or treatment.

News of the Week.

The Endowment of the Pasteur Institute.—The Pasteur Institute in Paris will shortly come into possession of a capital sum estimated at 30,000,000 francs ($6,000,000), the product of the estate of the late M. Osiris, which is now being realized. In 1903 M. Osiris founded a triennial prize of $20,000, to be given to "the person who had rendered the greatest service to the human race during the three preceding years." The prize was awarded to Dr. Roux, Director of the Pasteur Institute, for the discovery of the antidiphtheria serum. Instead of devoting the money to his own private purposes Dr. Roux made over the sum to the Pasteur Institute. This self-denying action so impressed the millionaire that he left the bulk of his fortune to the Institute as a token of admiration for the scientific attainments and self-abnegation of Dr. Roux. The Pasteur Institute is greatly in need of funds, and this endowment will firmly establish it as a monument worthy of the great master.

Contagious Diseases in Chicago.—During the week ending September 11 sixty-four cases of diphtheria and ninety-one cases of scarlet fever were reported—increases of fifteen cases of the former and fifty of the latter as compared with the preceding week. This increase in the number of contagious diseases cases has been particularly marked in the district, "back of the Yards" and on the West Side, and is due to unrecognized and concealed cases. The Health Department has taken the following steps to protect the children from these dangerous diseases: (1) Children from families having had a contagious disease in the house will not be allowed to return to school until two weeks after disinfection has been performed. (2) Every child admitted to school is to be rigidly examined for any symptoms of contagious disease.

Amebic Dysentery in California.—A recent report of the Public Health and Marine Hospital Service states that during the past eight months, December to July, 1909, fifty-five cases of amebic dysentery were admitted to Marine Hospital in San Francisco, sixteen of which are supposed to have originated in California.

Commission to Fight Bovine Tuberculosis.—It is announced that an international commission of twelve, seven Americans and five Canadians, has been named for the purpose of eradicating bovine tuberculosis. The members are: Chairman, Dr. J. G. Rutherford, Veterinary Director-General for Canada; Dr. M. R. Molar, Chief Pathologist of the Bureau of Animal Industry, Washington; Dr. Fred Torrence of Winnipeg, Professor in the Manitoba Agricultural College; Dr. Schroeder, Washington; Dr. Veranus Moore, Dean of the Faculty of Comparative Pathology, Cornell; Senator W. C. Edwards, Ottawa; ex-Governor Huard, Wisconsin; Louis Swift, Chicago, packer; J. W. Flavelle, Toronto, packer; Dr. Charles Hodgetts, Toronto, Chief of the Ontario Board of Health, and Dr. M. H. Reynolds, Professor of Veterinary Science in the University of Minnesota. Dr. Leonard Pearson of Pennsylvania was named, but he has died since the list was made out and his place is to be filled.

New Agricultural Law.—Beginning October 1, 1909, in Section 99 of the agricultural law of New York State, the words "equine" and "bovine" are added, and provision is made for the payment for diseased animals directed by the State's veterinarians to be slaughtered. For bovine animals the sum is not to exceed $75 each, and for equine animals not to exceed $120 each. This provision is added to the law: "If the meat of the slaughtered bovine animal shall be passed for use as food, under official regulations, the Commissioner of Agriculture is hereby authorized to sell the same, and the proceeds from the sale of the meat, hide, and other marketable parts of the said animal shall be paid into the State Treasury."

Hog Cholera in Utah.—A mild epidemic of hog cholera is reported to be existing in the neighborhood of Ogden, Utah. The city sanitary inspector and the butchers are cooperating to prevent the spread of the disease.

Opium Famine in San Francisco.—San Francisco's Chinatown for the first time in its history is threatened with an opium famine. Two important factors have contributed to bring about this condition. The United States Government, by absolutely prohibiting the importation of opium in a crude form, has sent the price soaring from $16 to $40 for a half pound tin, while the State Board of Pharmacy, by strict supervision of all drug stores and prompt punishment of all offenders caught selling opium in any form, has made it impossible to obtain morphine in any place in San Francisco except on a doctor's certificate. This has resulted in a great hardship to the slaves of the drug, many of whom have applied for admission to insane asylums where they may be cured of the habit.

Radium in Colorado.—Reports from Colorado Springs state that valuable deposits of uranium, the mother substance of radium, have been discovered at Woodland Park, a few miles west of Manitou, Col.

The Yawl "Andrew J. McCosh" Wrecked.—Early in September the yawl presented to Dr. Grenfell of Labrador by the alumni of Princeton as a memorial to the New York surgeon was wrecked in the Straits of Belle Isle. The yawl was manned at the time by Dr. John Mason Little, a graduate of the Harvard Medical School in 1901, and three Yale undergraduates. Her mast was carried away in a storm and fog, and the boat was sinking rapidly when Dr. Grenfell, in the *Strathcona*, chanced upon it, rescued the crew, and towed the *McCosh* to Cape Charles.

Bequests to the Blind.—Among many bequests to charitable institutions Miss Edith Rebecca Lord has left large sums in aid of the blind of England. Her entire residuary estate has been devoted to this purpose. She has placed it in the hands of trustees with instructions to found the "Edith and Norman Lord Pensions." These will amount to ten shillings a week and are to be paid to as many blind men and women in England as the income will allow. It is, however, laid down that the recipients must have become blind after their twentieth year, must be over thirty-five years old, and of good character, and must never have begged in the streets or other public places. Several blind men and women are also remembered by name and receive bequests running from $50 to $500. To Miss Beatrice Taylor is left $2,500, to be used in her discretion for the blind branch of the Sunbeam Mission, and the Trustees of the Gardiner Trust for the Blind in London receive $5,000, the income of which is to provide annually a concert and dinner for 200 blind persons, which is to be known as "The Norman Lord Dinner."

Benefactions in New York.—By the will of Mrs. Emma A. Tillotson of New York $126,000 is to be distributed among various charitable institutions of New York City. Among the beneficiaries are the Home for Incurables, New York Institution for the Blind, Home for Old Men and Aged Couples, St. Mary's Free Hospital, St. Luke's Hospital, and the Skin and Cancer Hospital.

Allegany Penitentiary Unsanitary.—An agent of the Federal Department of Prisons and Prisoners has reported to the Attorney-General that the Western Penitentiary of Pennsylvania is in a most unsanitary condition. The report says that "the population on the first of this month was 1,301. Of this number more than half are at all times idle, and more than half are confined two in a cell. The cells are unusually small, and the cots take up almost the entire length of each, the room for moving about being a space eight feet long and eighteen inches wide. There are more than 300 prisoners suffering from tuberculosis, and 79 cells are now occupied by those showing advanced stages of this disease. The prison is filled with vermin of all kinds, although the officials are making an effort to eradicate them. An unusually large number of the prisoners are of the lowest possible character, mentally and morally, and there is but one general mess provided for all. Almost universal complaint is made about the quality of food served, especially the meats." The conditions are so bad as to require the immediate removal of all Federal prisoners.

Essex Market Court.—A committee of the Grand Jury in New York has recently investigated the condition of the Essex Market Court and has reported that they found distressingly unsanitary conditions practically throughout the building. They found the detention pen in the police court an excellent breeding place for germs of tuberculosis and other diseases. They found that magistrates, complainants, prisoners, and court attendants all are exposed to serious disease through the necessity of holding court in this building. The committee subscribed to and desired to intensify the presentment made by the Grand Jury and recommended that the conditions be brought to the attention of the Commissioners of the Sinking Fund as a basis for a demand for a new building. They recommended also that the conditions be brought at once before the Board of Health for summary action and that copies of their report be sent to various officials, including the Police Commissioner.

Philadelphia Jewish Sanatorium for Consumptives.—A new sanatorium for tuberculous patients has just been opened at Eaglesville, Pa., about two and a half miles above Norristown. It comprises seventy acres of land overlooking Valley Forge. On this tract is a large farmhouse and a new barn. The former has been remodeled into an administration building, and four sheds accommodating eight persons each have been built, together with an infirmary with a capacity for ten persons. In addition, a central structure containing a dining-room, kitchen, laundry, and disinfecting room, and connected with the infirmary by a covered porch has been erected. An engine and power house is in process of construction. The farm can furnish the needed vegetables, fruit, and grain, and the sanatorium has its own cows, horses, and chickens. It can almost support itself from the products of the farm. Each of the sheds is divided into two compartments and has a sun parlor. They rest on cement piers ten inches from the ground. Ventilation from above is provided by means of a space between the roof and a stretch of canvas that forms the ceiling of the compartment. Further, options have been obtained on a ninety-acre farm in the neighborhood, and it is planned to divide this into small farms and encourage patients that have recovered to make their homes here and take up agriculture. The institution is nonsectarian and will receive only free patients. The visiting physicians are Drs. W. B. Stanton, Ward Brinton, M. Solis-Cohen, and A. J. Cohen.

The College of Physicians and Surgeons of Columbia University has begun its one hundred and first year with a total enrollment of 279 students, including eighty-five new members of the first-year class. The exercises were held in the main assembly room. President Nicholas Murray Butler delivered the address of welcome and Dr. Christian A. Herter, professor of pharmacology and therapeutics, spoke on "Imagination and Idealism in Medical Science."

New Hospital in New York City.—Plans have been filed for remodeling the old-fashioned four story and basement dwelling at 203 Second avenue for the proposed People's Hospital. The necessary improvements are to be made at a cost of $15,000 and will provide a dormitory on the main floor, wards and private rooms on the first, second, and third stories, and operating, sterilizing rooms, and laboratory on the top floor, and also a nurses' room.

The Guild Hospital of Stanford University, which was a cooperative institution run by the Stanford University student body, has passed out of existence. The equipment and patients have been taken in charge by the Peninsula Hospital Company, and will for the present semester be conducted by this concern until a new building designed for hospital purposes can be erected in Palo Alto. The new concern will take care of all students and university people, who pay the guild fee at the same rates as were charged by the old organization.

Unlicensed Dentists.—The District Attorney's office of New York City began a raid on unlicensed dentists recently, arrested two of the offenders, and issued warrants for thirty more. Investigation has led to the belief that there are over five hundred unlicensed dentists practising in Manhattan alone. A great many of these men have offices on the East Side. Some of the offenders have had elementary dental training in other States. Some of the men for whom warrants have been issued have been convicted before on similar charges.

Poisoning by Ice Cream.—A sudden epidemic of ptomaine poisoning occurred in Fulton, Ky., recently. The sufferers had all eaten ice cream at a certain restaurant and nearly all who had eaten ice cream there were affected. There were no fatalities.

Chicago Milk Supply.—During the week ending September 11 bacteriological examinations were made of 67 samples of milk taken on the streets, 32 being pasteurized and 35 raw milks. The average bacterial count of the raw milks taken on the streets was 4,870,257: of the pasteurized milks, 849,937. The pasteurized milks, therefore, showed an average of 4,029,320 fewer bacteria per cubic centimeter than the raw milks. The 12 samples of ice cream examined during the week averaged 41,024,167 bacteria per cubic centimeter.

Hospital Burned.—St. Caroline's Hospital, a two-story frame building in Redding, Cal., was burned recently. Seven patients were rescued in safety, but a nurse, Mrs. J. H. Hardinge, perished. Miss Constance Rainsberry, matron, saved herself by jumping from an upper porch. She was burned about the hands and feet, but not severely. When the fire was discovered it was burning through the roof. A patient aroused everybody in the building and Miss Rainsberry and Miss Bertha Lampkin, a nurse, saved the patients.

The Sea Breeze Fresh Air Home maintained by the Association for improving the Condition of the Poor, at Coney Island, closed for the season on October 1. In the last summer 22,687 women and children have been taken to Sea Breeze for one-day stays, and 4,171 for stays averaging between eight and ten days.

The Physician's Legislative League of New York was incorporated recently. The objects of the organization is to promote and stimulate a higher standard of professional ethics among members of the medical profession, to recommend the enactment and enforcement of laws tending to elevate the practice of medicine and surgery, and to oppose the passage of laws detrimental to the profession; also to arouse among physicians a regard for their rights in the profession and as citizens of the community.

The Tri-Professional Medical Society of New York, at its annual meeting, held September 21, 1909, elected the following officers: *President*, Dr. G. Morgan Muren; *Vice-Presidents*, Dr. A. H. Goelet and Dr. G. K. Dickinson; *Secretary*, Dr. W. T. Dannreuther, and *Treasurer*, Dr. E. D. Franklin.

The Dallas County (Ark.) Medical Society was organized recently at Fordyce. The following officers were elected: *President*, Dr. C. J. Marsh; *Vice-President*, Dr. O. R. Kelley; *Secretary*, Dr. T. L. Rives, and *Treasurer*, Dr. W. L. Worthington.

The Washington County (Vt.) Medical Association, at its eighth annual meeting, held on September 14, elected the following officers: *President*, Dr. O. G. Stickney of Barre; *Vice-President*, Dr. L. W. Burbank of Cabot; *Secretary*, Dr. E. A. Colton of Montpelier; *Treasurer*, L. A. Russlow of Randolph.

The Franco-American Medical Society of Rhode Island, at its annual meeting, held at Providence, September 15, 1909, elected the following officers: *President*, Dr. J. B. N. Dubeau of Providence; *Vice-Presidents*, Dr. J. B. Morrisseau of Warren and Dr. J. Edgar Tanguay of Woonsocket; *Treasurer*, Dr. F. A. Ruest of Pawtucket; *Secretary*, Dr. Alfred Poirier of Woonsocket; *Assistant Secretary*, Dr. Arthur Trottier of Providence.

Obituary Notes.—Dr. William C. Kraus of Buffalo died at the New York Hospital, on September 21, 1909, aged 64 years. He was a graduate of the Harvard Medical School in 1886 and was a well-known authority on diseases of the nervous system. Dr. Kraus was a member of the Erie County Medical Society and the New York State and American Medical Association.

Dr. Charles T. Wilbur of Kalamazoo, Mich., died on September 15, 1909, aged 74 years. Dr. Wilbur was a graduate of the Berkshire Medical College in 1860, and was a member of the Kalamazoo County and Michigan State Medical Societies. He was a veteran of the Civil War. For many years Dr. Wilbur had been interested in the care of the feeble minded and at the time of his death was the head of the Wilbur Home for the Feeble Minded, founded by him in 1883.

Dr. Urban P. Atkinson of Fort Atkinson, Wis., died on September 6, 1909. He was a graduate of the Northwestern University Medical School in 1862 and had practised in Wisconsin for nearly fifty years. He was a member of the Jefferson County Medical Society and of the State Medical Society of Wisconsin.

Dr. John W. Mitchell of Clarksville, Ark., was shot and killed on September 11, 1909. He was a graduate of the Jefferson Medical College in 1889 and was a member of the Johnson County Medical Society and the Arkansas Medical Society.

Dr. George Lafayette Martin of Greenville, S. C., died at his home on September 16, 1909, aged 55 years. He was a graduate of the College of Physicians and Surgeons of Baltimore and a member of the Greenville County Medical Society and the South Carolina Medical Association.

Dr. Leonard Pearson, Dean of the Veterinary Department of the University of Pennsylvania, and Pennsylvania State Veterinarian, died in Newfoundland, on September 20, at the age of 41 years. Dr. Pearson was graduated from the Agricultural Department of Cornell University in 1888, and in 1890 from the Veterinary Department of the University of Pennsylvania, and in 1890-91 he attended lectures in the veterinary schools of Berlin and Dresden. In 1891 he was elected Assistant Professor of the theory and practice of veterinary surgery in the University of Pennsylvania, and three years later he was promoted to the full professorship, and he was then also made Dean of the Veterinary School.

Dr. Thomas Hovey Gage of Worcester, Mass., died September 16, 1909, at the age of 84 years. He was a graduate of the Harvard Medical School in 1852. From 1886 to 1888 he served as president of the Massachusetts Medical Society. For many years he was a member of the medical staff of the Worcester City Hospital and at the head of the board of trustees of that institution. He was also a trustee of Memorial Hospital and for years a trustee of the Worcester State Hospital.

Dr. R. S. Forsyth, formerly of Escanaba, Mich., died at La Porte, Texas, on September 11, 1909. He was a graduate of the Detroit College of Medicine in 1892, and a member of the Delta County and Michigan State Medical Societies and the American Medical Association.

Dr. Barnard D. Eastman of Topeka died on September 14, 1909, aged 73 years. Dr. Eastman was a graduate of the College of Physicians and Surgeons of New York in 1862. He had held the position of Assistant Physician at the New Hampshire State Asylum at Concord, and at the government asylum at Washington, and of Superintendent of the State Insane Asylum at Worcester, Mass. At the time of his death he was Superintendent of the Kansas Insane Asylum and held a professorship in the Kansas Medical College at Topeka.

Dr. Thrond S. Egge of Moorhead, Minn., was murdered on September 6, 1909, by an attack from a supposed maniac. He was fifty years of age and a graduate of the University of Minnesota in 1893. Dr. Egge was a member of the Clay County Medical Society and the Minnesota State and American Medical Association.

Dr. George D. Cook of Vassalboro, Me., died

suddenly, on September 15, 1909, aged 68 years. He was a graduate of the Medical Department of Bowdoin College in 1866.

Dr. G. H. Grigsby of West Baden, Ind., died at his home, September 10, 1909, aged 27 years. Dr. Grigsby graduated from the medical department of the University of Louisiana in 1908.

Dr. George C. Harlan of Philadelphia was killed on September 25, 1909, by being thrown from his horse. Dr. Harlan was 74 years old and was graduated from the University of Pennsylvania in 1858 and was well known as an ophthalmologist. He was a member of the Philadelphia County Medical Society, the Medical Society of the State of Pennsylvania, and the American Medical Association.

Dr. E. Mills Baker of Jersey City died suddenly on September 26, at his home, aged 48 years. He was a graduate of the New York University in 1890. He was a member of the Hudson County Medical Society, the Medical Society of New Jersey, and the American Medical Association.

Correspondence.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

THE COMING SESSION—WOMEN HEALTH VISITORS FOR LONDON—A VOLUNTARY SCHOOL CLINIC—LATENT DIPHTHERIA—PROTOZOAL TROPICAL DISEASES—A POSSIBLE ENEMY TO THE MOSQUITO—OBITUARY.

London, September 10, 1909.

The Winter Session is upon us. That is the familiar greeting just now. The prospectuses of all the schools are in free circulation and the teachers seem all in hopes of a good entry.

The Local Government Board has circularized the sanitary authorities of London, reminding them that by the Act of 1908 they are empowered to appoint "suitable women to be known as health visitors" for giving advice on the care of young children, the promotion of cleanliness, and so on. Under the authority of the Act the board has issued regulations as to qualifications, mode of appointment, duties, and salary of any health visitors. It is thought desirable as a general rule that they should devote all their time to the work, and the salary is not to be less than £100 per annum. But the sanitary authority may, with the board's consent, appoint her to hold concurrently another post under the same control. The board hopes that sanitary authorities will take advantage of these powers.

While the question of school clinics is still being discussed an experiment is going on in East London which may show that voluntary aid may supersede official action. It is financed by a Committee for the Physical Welfare of Children. The County Council accepts no responsibility for it and has only permitted the use of a small room, not well adapted but at a nominal rent, for trying the experiment. The children found to need treatment at the compulsory inspection are, if the parents are willing and declare so in a form supplied, treated at this clinic. The committee thinks this treatment better in many cases than hospitals. Besides two doctors who attend at fixed times to prescribe, a trained nurse is employed to see that the treatment ordered is actually carried out. It has been found that parents neglect to do this at home, but the nurse does it at the school and, the parents learning this, will bring the children to the nurse when they would not take them to an out-patient department, where they might have to lose three hours in waiting. The head mistress of the infant department is also warden of a settlement close by, and she and her helpers visit the parents and, knowing them as well as their children, has the opportunity of instructing them without giving offense. It is said that the improved cleanliness of the children is remarkable. Any children too ill to attend school are visited by the nurse, and the parents gladly recognize the desire of the settlement's helpers to assist them.

The County Council does not favor school clinics. As I reported, arrangements have been made with some hospitals to which the profession as a whole strongly objects. The question of expense has been mooted, but that may cut either way. Voluntary clinics such as the one I have described could very well cope with the work, and there can be no reason why better accommodations should not be granted by the County Council to any such committee ready to utilize it.

A conference took place at Belfast between the sections of hygiene and laryngology in reference to latent infections of the diphtheria bacillus. Dr. Watson Williams treated the subject from a clinical point of view and regarded the disease as latent when the organism was found without obvious illness. In practice latent diphtheria was met with affecting the nasal cavities, fauces, mouth, external auditory meatus, skin, and genitalia. Pseudomembranous lesions of the respiratory tract might be diphtheritic or not, and the difference was only determinable by bacteriology. He admitted that nurses, surgeons, and other contacts might harbor virulent organisms without any symptoms of ill-health and without conveying infection, and he thought that organisms impinging on healthy mucous membrane were speedily removed. He did not think much of local applications, and the effect of antitoxic serums was uncertain, as the proportion of active substances varied so much and could not be calculated.

Dr. R. Buchanan treated the subject from the bacteriological aspect and said routine diagnosis depended on morphological characters on account of the expedition demanded, and so loss of accuracy occurred. To determine without doubt any instance cultures and inoculation tests must be employed, and they required four to six days as a minimum. The virulence of the organisms was not much different in latent cases and in others. The bacillus was very tenacious of its virulence, and attempts to reduce it had not been very successful, though it could be easily increased. When it obtained access to a membrane it seemed to remain for a time, whether it produced illness or not. Clinical cases and contacts showed no particular difference as to the period of its remaining.

Dr. Forbes then discussed the question from an administrative aspect.

Dr. Clark gave an account of measures adopted in outbreaks at Leeds.

Dr. D. Mackenzie thought nasal swabs, as well as throat swabs, should always be taken.

Dr. E. W. Goodall said that in 1893-1894, in London, bacteriology was not resorted to, yet the epidemic gradually abated. He did not discharge his patients until after several examinations gave negative results, but he got no better results than his colleagues who did not do so. He thought return cases were a negligible quantity. He did not recommend prophylactic injections of serum. They were not devoid of danger. It was desirable to settle whether swabbing of convalescents was advisable.

Various suggestions were made by other speakers, especially as to the taking and examination of material, the best ways of dealing with contacts and with latent cases, the giving of antitoxin by the mouth, the dependence on morphological characters, the virulence of the different forms, and the relations of the organisms to hygiene and administrative work.

The most interesting discussion in the Tropical Section was that on the persistence of the tropical diseases which are due to protozoa, opened by Dr. Daniels, who said all recent advances pointed to an alternation of the processes of multiplication—sexual and asexual. The disease-causing period was when asexual reproduction was taking place. But the sexual forms were, of course, injurious, as they were the transmitting agents from host to host. Repeated asexual reproduction might be expected to lead to degeneration of strain, but so far as human parasitic protozoa were concerned there was little if any evidence of this. It rather seemed that loss of virility took place even with indefinite asexual reproduction. It was true that protozoal infections did die out in man, but that was due to changes in the host—not to the parasites losing virility. In some cases a year in a cold country would see the end of the malarial parasites, in others three years might be required. There seemed to be some essential similarity between protozoan infections multiplying asexually and bacterial infections, and this fact should not be lost sight of. In countries where reinfection was common, a resistance was developed after four years' residence, and after ten years this had become so marked that it was quite an exception for reinfection to occur. This showed that a condition

had been established inimical to the parasite, but it was not permanent, and the immunity would be lost by a residence in a nonmalignant country, as shown by liability to recurrence on removal to a malarial district. This showed that the protozoa might be regarded as on a par with bacteria and that our efforts should be directed to increase resistance in man as much as trying to destroy the parasite.

Dr. Breint hardly thought the bacteria compared so closely with protozoa, but that while asexual reproduction might go on indefinitely, resistant forms developed which, after the disappearance of the antibodies restraining their action, might resume their asexual multiplication.

The difficulty as to the question of persistence of infection was admitted by Dr. Maxwell to be largely due to asexual multiplication in malarial countries. This rendered it necessary to study the point in this country. Several members maintained that change to a cold climate was the best, if not the only way, of getting rid of malaria. But this is not to be expected in a few months, for Dr. Cantlie mentioned that after returning to London he suffered for three years in the hot months and in the fourth year had severe neuritis, which resisted all treatment until his general health was improved.

Dr. Stone remarked on the failure of quinine in some cases, especially malignant tertian, and questioned whether the drug acted directly on the parasite or in some indirect way.

Dr. McCutcheon confirmed the frequent failure of quinine in malignant cases, especially in attacks of fever at intervals of two or three weeks, and other speakers held the same opinion.

A statistical report on the ordinary expenditure of sixty-six London hospitals for 1908 has just appeared. It is thought that such reports which have been made since 1803 are of service by comparing the work cost of different institutions and so encouraging all efforts at economy. The large and small general hospitals form two groups and special hospitals a third. In each main items of cost are taken and compared with those of the group average, and another table shows the total expenditure at each hospital on all the items lumped together. The total expenditure of the larger hospitals shows considerable differences, *e.g.* Charing Cross £18,322, Guy's £65,775, the London £110,790, Middlesex £33,870.

Dr. J. Mitford Atkinson, principal civil medical officer at Hongkong, relates in the *Lancet* what may prove to be an important discovery, viz., a possible natural enemy of the mosquito. Some specimens were sent last year to the Tropical School here and recognized as *Dolichopodides,* but were too damaged on arrival to identify the species. More have since been sent and identified by Mr. Austen, of the British Museum, as belonging to the species of *Lispa Sinensis* (Schiner) of the family of flower flies—*Anthomyidæ.* They were seen greedily devouring the larvæ of mosquitos. Drawings of the fly are given in the *Lancet.* Dr. Atkinson adds that further investigation is required, but he left for England in May last.

Sir Stephen Mackenzie, consulting physician to the London Hospital, died on Friday evening, the 3d inst., aged 65. He was a student of the London Hospital and qualified in 1869, afterward going to Aberdeen, where he took M.B. 1873 and proceeded to M.D. in 1875. He obtained the registrarship of his hospital during this period, an office demanding no small work, but arduous work was the characteristic of his life. He was appointed assistant physician in 1874, and from that time onward his strenuous work carried him on to success, both as a teacher and a physician. In 1879 he was elected F.R.C.P. He held many other appointments, but his chief was physician to the London Hospital and lecturer there on medicine and clinical medicine. He delivered the Lettsonian lectures of the Medical Society in 1891 and gave the annual oration in 1902. He contributed freely to the journals and the transactions of the societies, to Quain's and Heath's dictionaries, and to Allbutt's System. He had retired for some years on account of asthma, to which he succumbed after long sufferings borne with fortitude.

Surgeon-General E. R. Butler, I.M.S., retired, died on the 6th inst. in his seventy-seventh year. He was formerly presidency surgeon at Bombay and surgeon to the European Hospital, and held other important appointments.

Dr. Maxwell Ferguson died on the 27th ult. in his ninety-second year.

Dr. T. Bridgwater, J.P., LL.D., died on the 6th inst., aged 85. He graduated at the London University in 1852. He will be remembered by generations of old Harrovians, as he was one of the medical officers of the famous school for thirty-five years.

THE SIXTEENTH INTERNATIONAL MEDICAL CONGRESS.

(From Our Vienna Correspondent.)

APPENDICOSTOMY FOR AMEBIC DYSENTERY—PATHOLOGY OF GASTRIC ULCER—THYROID EXTRACTS—TYPHOID SPINE—INFECTIVE ARTHRITIS—OPERATION FOR ARTHRITIS DEFORMANS—NERVE ANASTOMOSES—HEMATOLOGY IN SURGERY—THEORY OF VISION.

BUDAPEST, September 4, 1909.

ENGLAND and the United States were well represented at the International Congress, the delegates from the Anglo-Saxon countries presenting a number of valuable contributions.

Drs. James M. Anders and William L. Rodman said that the subject of the treatment of amebic dysentery, particularly in its bearings upon surgical procedures, assumed importance in view of the utter hopelessness of a certain proportion of chronic cases, and also because of the widespread prevalence of the disease, even in subtropical and temperate regions. The fact that an unsterilized water supply is the principal source of infection deserved especial emphasis. The danger of eating green vegetables and fruits, which had either been fertilized by the Oriental method, *i.e.* with human excrement, or cleansed with contaminated water, must be recollected. In the treatment rest was important. Magnesium sulphate was recommended to lessen the pain and tenesmus by removing the hardened fecal masses and inhibiting rather than exciting undue peristalsis. Ipecacuanha early gained popular favor only to fall from its enviable position. It was reintroduced by Sir Patrick Manson, who had expressed the belief that in this drug we had a remedy possessing specific virtues. It might be questioned whether colonic irrigation *per se, i.e.* without surgical intervention, had in its last analysis given more encouraging results than the ipecacuanha treatment properly employed. The simple fact was that not all cases of chronic amebic dysentery yielded to either rectal lavage or ipecacuanha. It was desired to place on record a case in which appendicostomy followed by irrigations with a solution of quinine resulted in a remarkable cure. They favored doing the operation in two stages, believing that it was best not to open the appendix until firm adhesions had taken place between the cecum and parietal peritoneum.

"The Etiology and Pathology of Gastric and Duodenal Round Ulcer" was the subject of a new series of experiments reported by Dr. Fenton B. Turck of Chicago. He said that positive feeding experiments with *B. coli* indicated that alterations in the toxic state of the alimentary canal with consequent changes in the blood, such as diminished activity of the antiferments, might be responsible for ulcer formation. To produce acute ulcer, from 500 to 2,000 c.c. of bouillon cultures of *B. coli* were fed to dogs daily for three or four months in connection with the usual meat diet. The colon bacillus was at no time found in the blood, and few symptoms of systematic disturbance appeared. The blood serum, on the other hand, agglutinated *Bacillus coli* in high dilutions, the coagulating time was slower and hemolysis was present. Such an ulcer terminated in the usual perforation and hemorrhage. If the feeding process was interrupted at the end of six or eight weeks, the ulcer healed. Resumption of the feeding of *B. coli* in large quantities was followed by violent reactions—diarrhea, bloody flux, and death, all of which showed that increased susceptibility was produced during the period when feeding was suspended. If the feeding was resumed in small quantities and at intervals, no anaphylaxis occurred, and the result was typical chronic deep ulcer of the stomach or duodenum. *In vitro* cultures did not furnish conditions for the study of bacteria like those associated with infections of the colon and intestines, and injections and cultures in any living animal would be just as complicated as in the dog or in the human. The fetus of an animal suggested itself as an appropriate culture chamber, and on account of the facility of procuring, the fetal pig had been used altogether in this series of experiments. It furnished one of the very best culture chambers for anaërobes, and with slight modifications was equally good for aërobes.

Drs. Reid Hunt and A. Seidel of Washington discussed pharmacopeial preparations of the thyroid gland, and said that this thyroid was included in several pharmacopeias. The United States Pharmacopeia required (1) the presence of combined iodine, and (2) the absence of certain water soluble iodine compounds. No pharmacopeia had a standard for strength for the drug, which varied greatly. The new evidence that value of thyroid depends upon the amount of iodine was given. The chemical and physiological methods for distinguishing between iodine present in thyroid and that present in other forms of combination were described. The physiological method (viz. the increased resistance of mice to acetonitrile caused by feeding thyroid, but not—or to a much less extent—by feeding other iodine compounds) was apparently more sensitive than chemical methods. This test was applicable for detecting thyroid in secret medicines and in the blood in Basedow's disease. The authors recommended that pharmacopeias require from 0.1 to 0.2 per cent. of iodine in dessicated thyroid.

Dr. J. Halpenny of Winnipeg, Canada, reported a case of typhoid spine, citing a case of typhoid fever, followed, during convalescence, by a severe spinal condition, occasioned by driving over a rough road. The temperature reached 104 degrees. There was marked pain in the lumbar region, but no deformity. The case ended in perfect recovery. He reviewed seventy-two cases reported by various authors. The following points were discussed: Age, sex, location, pain, temperature, leucocytes, local signs, sensory disturbances, reflexes, muscles, deformity, *x*-ray reports, caries, length of disablement, and treatment. The author concluded that there was a definite local pathological condition, and that it was a rare affection, with a good prognosis, particularly if treatment was instituted early.

Dr. J. B. Murphy of Chicago said that infective microorganisms admitted to joints were usually overcome if unassociated with trauma. The same microorganism admitted without trauma would cause no reaction, while that admitted with trauma would produce a fatal termination. The destruction of joints by infection depended on the virulence of the infection, diminished individual resistance, trauma associated with infection, duration and tension under which the products of infection were held in the joint, and the presence of foreign bodies. Acute, infective, purulent synovitis following punctures, bullet wounds, fractures, injuries, and hematogenous infections could practically all be cured without drainage and without ankylosis. Drainage of a joint was practically always a surgical crime. Resistance to infection in joints could be autogenetic from hemorrhage and trauma, induced by chemical irritants of definite types, or when infection was present absorption of its products could be induced by chemicals producing increase in the polymorphonuclear leucocyte. All joints to be subjected to surgical procedures should be rendered locally immune.

Dr. H. Albee of New York presented a report of an operation for advanced arthritis deformans (osteoarthritis), paralysis (dangle joint), and certain select adult cases of tuberculosis of the hip joint. Firm ankylosis was produced by the removal of a part of the superior hemisphere of the head of the femur and the transformation of the acetabulum into a flat surfaced roof. These fresh surfaces were then brought into close apposition, sometimes by the correction or over-correction of the deformity, if one existed. Twenty-two cases, twelve of which were the author's, were reported. The results had been very satisfactory. Pain had been entirely relieved in every one of the author's cases.

Mr. A. H. Tubby of London read a paper on the treatment of distal paralyses by nerve-anastomosis. The forms of distal paralysis treated were traumatic, and those due to anterior poliomyelitis. The results showed that the time taken for regeneration was very variable. But the writer's conclusion was that the longer before the operation, the slower would be the signs in appearing after it. No case could be regarded as hopeless, even if no evidence of regeneration was present three years after operation. Eight cases were quoted. Two were of traumatic origin and six were due to anterior poliomyelitis.

Dr. Frederick E. Sondern of New York read an instructive paper on the value of examination of the blood in surgery. He said that the grade of neutrophile polynucleosis was a valuable factor in the diagnosis of acute inflammatory lesions. It gave increased significance to the leucocyte count, and by a determination of the relation between the two information of greater value for diagnosis and prognosis was obtained. The neutrophilic polynucleosis was a sign of toxic absorption, while the leucocytosis measured the resistance of the organism. A knowledge of a disproportionally high neutrophilic polynucleosis in comparison to the leucocytosis was of especial value, inasmuch as it indicated the presence of a purulent exudate, and the necessity of early surgical interference on account of the low body resistance. The method, like all laboratory methods, had its limitation, but with a thorough familiarity with its limitations and the exceptions to which it was subject, the method was a diagnostic and prognostic aid of the highest value in surgery.

Dr. Edridge Green of London, in discussing the theory of vision, said that a ray of light impinging on the retina liberated the visual purple from the rods and a photograph was formed. The rods were concerned only with the formation and distribution of the visual purple, not with the conveyance of light impulses to the brain. The decomposition of the visual purple by light chemically stimulated the ends of the cones (very probably through the electricity which was produced), and a visual impulse was set up which was conveyed through the optic nerve fibers to the brain. There were cases in which the visual purple was differently constituted and was not sensitive to certain rays at one or both ends of the spectrum. The character of the impulse set up differed according to the wave length of the light causing it. Therefore in the impulse itself we had the physiological basis of the sensation of light, and in the quality of the impulse the physiological basis of the sensation of color. But though the impulses varied in character according to the wave length of the light causing them, the color perceiving center was not able to discriminate between the character of adjacent impulses, the nerve cells not being sufficiently developed for the purpose.

Progress of Medical Science.

Boston Medical and Surgical Journal, September 16, 1909.

Fatty Infiltration of the Liver in an Infant of Three Months.—The patient of C. A. Pratt was a normally born infant, fed on artificial food after the first seventeen days. It did well for about three months, when it began to have poor appetite, and for a short time was obliged to be fed on a new food supply during extremely hot weather, when she developed evidences of extreme indigestion. Examination showed a distended abdomen and an enlarged liver. The symptoms of indigestion continued and she died in about a month. An autopsy was held and a typical fatty infiltration of the liver was revealed. The cause of the initial toxemia was undoubtedly the new food taken in the hot weather. It contained some cream, but the liver was undoubtedly enlarged before this food was begun. It does not seem to the author that this toxemia would have proven fatal had the condition of the liver been normal, so that the ordinary body metabolism could have been carried on, nor does it seem probable that if the mother had been enabled to continue the nursing that the liver lesion would have developed. He rejects the theory of a congenital condition. The child never had any jaundice. The liver seemed to fill the entire abdomen. The case is reported on account of the apparent rarity of such a large liver in such a small child.

The Relationship between True and False Angina Pectoris.—This question is discussed by G. G. Sears, who is inclined to regard the general condition as a vascular colic of reflex origin in some circumscribed area of the heart and possibly in its milder manifestation of the vasa vasorum in the ascending aorta, with resultant ischemia in the parts supplied. If this be true the mechanism by which the attacks are induced is essentially the same in all forms, and hence a distinction between the true and false must rest on the presence or absence of some pathological lesion on differing clinical symptoms, or on a combination of the two. In some fatal cases, however, no lesion has been found. Myocardial changes often escape detection, even after the most careful examination, and a spasm of sufficient extent and intensity may prove fatal in healthy vessels and in a normal heart. It is equally difficult to classify those cases occurring in middle-aged or elderly persons who are undoubtedly the possessors of some cardiac or valvular lesion and who yet lose their symptoms, which never return. There is hardly more reason to classify cases of angina according to the presence or absence of cardiac disease than there would to separate

cases of pneumonia on the same basis, though the condition of the heart may determine prognosis. Before we can make any progress in the differentiation between true and false angina, our knowledge of the essential causes of the paroxysm must become more definite. Until then our use of the terms true and false must be regarded less as an expression of our knowledge than as a useful cloak for our ignorance.

New York Medical Journal, September 18, 1909.

Recurrent Hordeolum.—A. Bray says that the ordinary herdeolum requires, if accompanied by severe pain, a small incision followed by hot fomentations. A solution of boric acid and biborate of soda in distilled water will then effect a cure. In multiple and recurrent cases the hot fomentations are followed by a mixture of arnica, laudanum, and dilute Goulard's extract in water, applied on absorbent cotton. After the disappearance of the sty he uses a weak ointment of bichloride (gr. ⅛) to 2 drams of white vaseline. This should not be merely smeared over the lids, but should be applied with gentle massage every night. Prior to the application of this antiseptic ointment hot compresses should be applied to stimulate the circulation of the margin of the lids. While an ordinary sty does not always require the correction of any errors of refraction it is always an essential procedure in the recurrent type. It is very often a contributory factor in the development of stys. Having corrected any error of refraction under a mydriatic an antiseptic nasal wash is ordered. A teaspoonful of boric acid in a glass of water to be snuffed up twice daily is a good, simple procedure. The constitutional aspect of the case must, of course, be remembered. The author usually employs compound syrup of hypophosphites with good result. In order to keep the bowels in good condition the fluid extract of cascara is added. Under the foregoing régime the most intractable cases will usually yield in a month's time.

A New Diagnostic Skin Reaction in the Acute Infections.—The method employed by L. K. Hirschberg is as follows: The hairless portion of the arm or forearm is cleaned with ether. No alcohol, soap, water, or other disinfectant is used. Five or more scarifications are made (the number is dependent on the varieties of vaccines used) with a small metal screwdriver-like lancet. The blade is 0.3 centimeter broad and half-moon shaped. This makes an ideal scarifier when given the rotary motions of a screwdriver. It is so tempered that the half-moon blade may be repeatedly sterilized in an alcohol flame without injury. The scarifications are made in two parallel columns an inch apart. Between each vaccination the scarifier is sterilized in the alcohol flame, thus preventing contaminations or mixed vaccines. The ends of the tubes containing the various vaccines are wiped with sterile gauze to clear away the spicules of glass. The usual amount of the various vaccines taken have been 2,000,000 gonococci; 40,000,000 *Staphylococcus aureus;* 4,000,000 streptococci; 8,000,000 colon bacilli, and 4,000,000 typhoid bacilli. In each case the amount corresponds to 0.1 c.c. of the stock vaccines of manufacturing laboratories. The skin is scarified with sterile water, a salt solution of physiological strength, or 50 per cent. glycerin and 1 per cent. phenol in isotonic salt solution. This is used as a control. Usually five other vaccinations are made. The types of organisms used depend upon the suspected infection. Several illustrative cases are summarized.

Treatment of Mechanical Constipation and Obstipation.—S. G. Gant writes an elaborate article on this topic, dividing the condition into chronic, habitual, spastic, and mechanical. Habitual constipation can, as a rule, be permanently relieved by rectifying errors in the patient's diet, educating him as to his manner of living, and mapping out for him a systematic course of psychotherapy, exercise, hydrotherapy, massage, mechanical vibration, and electricity, alone or in combination. Spastic constipation is most frequently induced by mucous colitis, and can be relieved only by removing the underlying condition. The most common causes of the mechanical form are congenital deformities, strictures, tumors, foreign bodies, fecal impaction, adhesions, angulations, volvulus, diverticula, enteroptosis, colonic dilatation, hypertrophy of O'Beirne's sphincter, hypertrophy of the rectal (Houston's) valves, hypertrophy of the levator ani and the sphincter ani muscles, deviated coccyx, and diseases of the rectum and anus. The removal of any of these conditions is the first step in treatment, and the various surgical procedures for the varying lesions are described in full by the author, who says that the malformations and diseases of the intestine are not always easy to discover, but when their existence has been ascertained they can usually be removed by competent surgery.

Journal of the American Medical Association, September 18, 1909.

Infant Feeding.—H. D. Chapin says the science of infant feeding consists in knowing why certain things should be done or should not be done and the effects of different procedures. The art of infant feeding comprises the methods employed. Most of the literature is related to the art, and many diverse methods have been proposed. The infant is an animal and subject to the general laws of animal nutrition and, like other young mammals, is as regards its digestion in an embryonic state for some time after its birth. The food supplied by the mother has the property of changing its physical form when it comes in contact with the gastric secretions. It assumes a more or less solid form in the stomach, and the character of this solid varies as the stomachs of the different species vary, the milk of rapidly growing animals containing more protein than that of animals of slower growth. The adaptation of milks to the infant stomach must be done according to biological laws which call for a knowledge of the structure and functions of the digestive tract, together with the peculiarities of the milk furnished. A chemical analysis of milk will show its ingredients and to a certain extent their potential food values. Farther than this, chemistry cannot go. While the fats and carbohydrates are a good deal alike in the different milks, proteins are essentially different, and we must study the reactions of the proteins to the digestive secretions and then examine these reactions in relation to the growth and development of the digestive tract—in other words, investigate the question biologically before we can understand the problem. A certain portion of the proteins of all milks coagulates on coming in contact with rennin or rennin and acid, but the manner and extent of this coagulation is in direct relation to the proper evolution of the animal. While there are many grades of coagulability in the milks of different animals, for practical purposes we may distinguish three grades and consider their significance. In the ruminant herbivora, such as the cow and goat, the protein coagulates in solid tough masses that cannot easily leave the stomach, where digestion largely occurs. In the nonruminant herbivora, such as the horse and the ass, the protein coagulates in gelatinous masses that can easily leave the stomach, and digestion is largely intestinal. In human milk the curd is thrown down in flocculent masses midway between the two just described and the digestion is largely carried on in the intestines. Biological science thus shows that the protein must curd in a specific way in each species of animal, it being the least interchangeable of the components of milk. We must also remember that the protein has a developmental as well as a nutritive function to perform, and we must not, while putting all food in a soluble form for quick absorption, neglect to give proper work for the secretions and musculature of the digestive organs. Chapin gives illustrations showing how we should adapt milk for artificial feeding. We should allow for some of the protein to be thrown down in more or less solid form to develop the motility of the digestive tract. If there is evidence of weakness there already by the appearance of curds in the stools, a substance like citrate of sodium added to the milk may be scientifically indicated for a time, though as a routine measure for normal infants it would be unscientific. Antacids are also contraindicated as routine measures, as there is little acid secreted in the infant's stomach, though they might be indicated to correct abnormal conditions of acidity.

Medical Versus Legal Responsibility.—A. Gordon criticises the legal test of responsibility, *i.e.* the knowledge of right and wrong, which is still influential in legal decisions. He goes over the various forms of insanity in which the question of responsibility may arise and shows how, with the loss of control which they involve, responsibility cannot be admitted in a scientific consideration of the subject, *i.e.* the legal test of right and wrong cannot be applied. On the other hand, in cases of voluntary intoxication the knowledge of right and wrong for the moment may be lost and yet the individual cannot be considered in the same category, and here also the legal test will not apply. The insane man may recognize the distinction perfectly, may appreciate the unlawfulness and immorality of his act, and yet be irresponsible on account of his inability to control conduct. The sane man, however, may intentionally make himself intoxicated and in this condition commit a crime, but, if he is acquitted or only slightly punished on the ground that he was unable to control himself from drink, or was too intoxicated to know right from wrong there will be a miscarriage of justice. Gordon also holds that we cannot consider a man completely normal and responsible during a lucid interval of insanity or in the

remission say of general paresis, nor would he consider the legal test of knowledge of right and wrong entirely applicable in cases of dipsomania and epilepsy.

Syphilitic Pseudoparalysis.—L. T. Royster calls attention to a manifestation of hereditary syphilis which exhibits itself during the first few months of life in a failure, disinclination, or inability to move one or all of the extremities, which is variously alluded to in the literature as syphilitic pseudoparalysis, Parrot's paralysis, or merely described under the pathological condition syphilitic epiphysitis. It belongs under the general class of osteochondritis. The gross appearances depend on the stage or degree of cartilaginous inflammation. Sometimes there may be a swelling or color at the junction of the bone or there may be complete separation and a false joint. The symptoms attracting attention are that the child does not use one or more of his limbs. Both legs or both arms may be involved, but it is not described that all four are at once affected. In other cases there is a more or less spastic condition, the joint resisting motion, and the child crying with pain when handled. The diagnosis is very important, since epiphysitis is said to be the most common manifestation of hereditary syphilis and may be the only one. There are but four conditions with which it is likely to be confused—scurvy, infantile paralysis, septic epiphysitis, and brachial birth paralysis. Scurvy is rarely seen before the fifth month, is always bilateral, and affects the shaft of the bone, while this disease appears rarely after the third month. Infantile paralysis is also later in appearing, is frequently epidemic, and the history, onset, and course are decidedly different. In septic epiphysitis the constitutional symptoms are pronounced and the temperature elevated. The diagnosis from brachial birth paralysis seems most important and difficult, especially when the arms alone are involved. There is usually, however, a history of difficult labor with heavy traction in Erb's paralysis, though it has been known to occur after normal labors. Erb's is usually unilateral, while the other is more apt to be bilateral. Either kind of paralysis may appear at the same time, but in cases with separation or if the characteristic bony ring can be felt, the diagnosis is easy. In Erb's paralysis the reaction of degeneration may be present early and there is a selection of definite groups of muscles; slight tumors are sometimes seen also at the point of the tear in the nerve fibers. Some patients with Erb's paralysis improve spontaneously, and in some cases of the other form there may be a permanent deformity if they go untreated, which in later life may not be distinguishable from the deformity from Erb's paralysis. The flaccidity may very closely resemble that of Erb's paralysis. Two typical cases are reported. The treatment should be specific, by inunction.

Nodular Opacity of the Cornea.—J. Green, Jr., reports a case of this rare affection which he thinks deserves the careful attention of ophthalmologists. It is ushered in by moderate photophobia, epiphora, and, occasionally, a foreign body sensation. There is no true pain, only an ocular discomfort accompanied by diminution of visual activity. Throughout the whole course of the disease there is a notable absence of active inflammation, and it is essentially chronic and rebellious to treatment. He points out the difference between it and a number of other conditions, such as superficial punctate keratitis, which is always inflammatory, the keratitis masculosa of von Reuss, and nummular keratitis of Stellwag, which are both of good prognosis, grill-like keratitis which is distinguished by the very definite network, syphilitic and eczematous keratitis, etc. The histological findings have been somewhat varied, though presenting some points of similarity. He is inclined to accept Wehrli's opinion that some of these cases are tuberculous, especially in the light of the case he here reports. The patient with a very clear family history of tuberculosis who himself had had a severe cutaneous tuberculous infection, had presented himself with a typical nodular opacity of both corneas. In the absence of any etiological factor aside from tuberculosis the general and local reaction to the diagnostic tuberculin test and the clearing up of the internodular opacities, softening of the nodules, and improved vision under tuberculin treatment, all lead him to the belief that the case is one of attenuated corneal tuberculosis.

The Lancet, September 11, 1909.

Malaria Treated with Injections of Quinine.—G. W. Young reports three cases of malaria occurring in young males. In all the stomach was intractable to quinine and they were given injections of ten grains inserted deep into the gluteal muscles, after which the stomach became more tolerant and they were quickly cured. The salt used was the acid hydrochloride. One of the cases was of the tertian type and the other two, quotidian.

The Use of the Ultramicroscope for the Early Diagnosis of Syphilis.—Commenting on the difficulty in finding the *Treponema pallidum* in the early stages of syphilis, H. W. Bayly advises the use of the ultramicroscope, which substitutes trans- or rather oblique illumination for direct illumination in making examinations of scrapings from suspicious sores, etc., and finds that scraping from primary or secondary sores in untreated cases generally reveals the organism. All lesions do not show them in equal numbers. They are most numerous in mucous plaques, scanty in chancres, and rare in the roseolar rashes, though frequently found in some of the papular rashes. The technical procedure is thus described. It is very simple, the chief difficulty being the adjustment of the apparatus (light, condenser, mirror, and ultramicroscope). A small drop of distilled water or normal salt solution is first placed on the slide, and then the margin of the chancre, mucous plaque, or papule is gently scraped and the serum expressed by pressure, and a small quantity of this mixed with the drop of water on the slide. The distilled water causes the organism to swell, when it can be more easily seen than in normal saline. A large cover-glass is now applied in the usual way and pressed down firmly, so that only a thin layer of fluid remains between the cover-glass and slide. A drop of immersion oil is now placed underneath the slide, which must be sufficient to fill the space between the lower surface of the slide and the upper surface of the ultramicroscope condenser, and a second drop is placed on the cover-glass in the usual way; the preparation is now ready for examination. The blood cells, bacteria, spirochætæ, etc., will be seen as glistening refractive objects on a dark background.

The Etiology of So-Called Congenital Dislocation of the Hip Joint.—R. Thompson notes the much greater frequency of this condition in girls than in boys. It is generally directly due to pressure exerted on the hip joint during the adoption of the erect attitude of such a nature as to produce displacement of the head of the normal femur from a nearly normal acetabulum. The usual history of such a case is this: The patient is a well-developed girl in whom the condition becomes more marked as she assumes the erect attitude. The child is rarely seen until the third or fourth year, when the physician has to decide between the congenital or acquired formation of the malady. He generally chooses the former, basing his opinion on the results of a few dissections, on cases seen at a very young age, and on certain pelvic conditions. The author really believes that the condition arises after birth from certain anatomical peculiarities of the female pelvis. When the erect attitude is assumed the female hip joint is not so well calculated to resist the upward thrust of the femur as is the male joint. It depends much more for its security on the rim of the acetabulum, which is cartilaginous during the first two years of life, than does the male joint. In other words, the head of the male femur is much more securely fixed in the hip bone than is the head of the female. The acetabulum lies in the male hip bone, while in the female it rather rests upon it. Moreover, the joint in the female works at a greater mechanical disadvantage. Hence the so-called congenital dislocation is really in many cases a static dislocation. The author illustrates his meaning by some well-defined diagrams. With regard to treatment, two classes of cases may be made. In the first anatomical reduction can be easily and permanently accomplished, while in the second this is impossible, even under the most skillful manipulaion. Illustrative cases are given. If the author's views are true, many other changes which have been regarded as primary and as possible causes of the dislocation are really secondary. These are enumerated as follows: Small and triangular acetabulum, small os innominatum, head of femur flattened and smaller than usual, shortening and anteversion of the femoral neck, coxa valga, hour-glass constriction of joint capsule, stretched or absent ligamentum teres, and shortening of leg below knee. These conditions are discussed seriatim by the author. He summarizes his views as follows: The history of a well-developed girl with dislocation of the hip rarely goes back before the adoption of the erect attitude. The fact that the child is well developed is a considerable factor in favor of the condition being static rather than congenital. The female hip joint is weaker and acts at a greater mechanical disadvantage than does the male. The congenital theory entirely fails to explain the greater preponderance of the lesion in females, but the preponderance is explained by a reference to the comparative anatomy of the joint in the two sexes. Moreover, the suggestion that the condition is static more easily explains the different conditions which may be met with.

British Medical Journal, September 11, 1909.

On the Value of Surface Signs in the Diagnosis of Deep-Seated Disease.—C. L. Isaac calls attention to

several typical cases of gastric ulcer and notes that when hyperesthesia is found on the abdomen a spot also exists over the spinal column in the region of the dorsal branch of the cutaneous nerve affected. In cases of duodenal ulcer definite spots of hyperesthesia may be found just above the umbilicus, and the author believes that this reaction occurs only in acute ulceration. It is found at or near the middle line, both ventrally and dorsally, that is, at the cutaneous nerve terminals corresponding to that segment of the cord which supplies the sympathetic nerve or nerves to the viscus involved. In support of this statement it may be said that in the duodenal cases the tenderness was found near the umbilicus, considerably lower than the gastric tenderness, whereas it is possible for a gastric ulcer to be anatomically lower than a duodenal one; but as the stomach is embryologically a vertical organ, the duodenum receives its nerve supply from a lower segment of the cord. In general the author contends that cutaneous hyperesthesia is of considerable value in the diagnosis of acute ulceration of the viscera; that the neuromuscular reaction is of some value in the diagnosis of inflamed viscera; that myototic irritability is by no means a negligible feature, and that the suggestion that there is a neuropigmentary sign in the skin of visceral disease proves that the superficial evidence of deep-seated disease is a far larger one than at first seems.

Oriental Sore of Northern India a Protozoal Infection.—R. M. Carter describes his experiences in the study of this malady, believing that though the common fly in the East may not be the actual invertebrate host that infects men with Oriental sores, the parasite does develop within the gut of the musca domestica. This development to the monadine form is therefore probable in other flies and the actual biting flies, ticks, or mosquitos that transmit the disease should be sought for. Furthermore, it is necessary to determine whether members of the herpetomonas and erithidia genera are able to develop monadine forms in other hosts than are at present usually accredited. The typical appearance of this sore is a small red spot appearing on some exposed surface of the body. The top of this is scratched off and a thin serum exudes, forming a yellow scab. In forty-eight hours this is fringed by a thin inflammatory line and the scab grows slowly at the expense of the surrounding tissue. If the scab is removed a shallow ulcer is revealed. Infected spots occasionally appear beyond the inflammatory line, and eventually a deep ulcer is formed, its base covered with indolent granulations, its walls eaten out and the circumference of the sore red and angry looking. After some months cicatrization sets in at the side of the ulcer. This may break down, but eventually overcomes the lesion, which heals up, leaving a dead whitish-blue scar.

The Intensive Treatment of Syphilis by Aachen Methods.—R. Hayes describes the plan followed at Aachen, dwelling upon the attention paid to details. All the organs of the body are carefully examined. The morning begins with from one to three glasses of sulphur water, followed by the bath, the temperature and time of immersion being carefully adjusted to the patient and the type of disease. This is followed by rest and breakfast in bed. Later comes the application by an expert rubber of a one-third strength mercurial ointment for twenty to forty minutes, the quantity and site of inunction being varied according to circumstances. The thighs, arms, calves, and back are treated consecutively from day to day. The groins and axillæ are avoided. Great stress is laid on oral hygiene. These measures permit mercury to be given without gingivitis or salivation up to a causation of general lassitude, drowsiness, or even intestinal cramps. All diet calculated to produce loose evacuation, such as white wine, uncooked fruit, and vegetables, etc., are forbidden. For cases within the first two years of existence about six months are required for a cure, the courses of treatment lasting from four to six weeks, with intervals of rest. During this time some tonic or preparation of iodine is used with advantage. The sulphur water of the baths obviously assists the mercury. The remedy is introduced by inunction through the lymphatic system, which is the stronghold of the treponema, and enters the system over a large area. Hence the rapidity with which the earlier symptoms vanish. In late stages, such as those with cerebrospinal lesions, the remedy is applied directly to the back and is assisted somewhat by the inhalation of the mercury volatilized by the skin.

Deutsche medizinische Wochenschrift, Aug. 19 and 26, 1909.

Cholecystectomy for Typhoid Carriers.—W. Loele discusses the frequency and the cause of typhoid carriers. Infection through nasal secretions are unknown. It is possible that a typhoid angina may be a source of contagion. Excretion of bacilli by way of the urinary tract is not rare, but the intestine is by far the most common source, while the gall-bladder is generally considered to be the primary seat of the organisms. Loele raises the question whether, this being the case, cholecystectomy might be a justifiable procedure to overcome the tendency to being a carrier, and thus a menace to humanity. He reports in full a case of a typhoid carrier who developed a cholecystitis, was operated on, died, and was carefully studied. In this case the cystic duct was completely obstructed by a gallstone, so that no fluid could pass up or down, a condition which appeared to have been of long duration. In this case it was impossible for the typhoid bacilli which were being passed from the bowel to have come from the gall-bladder. The author concludes his paper as follows: In a case of a typhoid carrier that had passed typhoid bacilli with the stools for three months following typhoid fever in whom cholilithiasis and empyema of the gall-bladder occurred (agglutination of the blood serum 1:2000) it can be stated, on the grounds of the findings at operation and at autopsy, that the excreted typhoid bacilli did not originate in the gall-bladder, but in either the gall-ducts or the intestine. Typhoid bacilli were demonstrable neither in the urine nor in the blood, nor in the organs examined (spleen and liver). Operative procedures to overcome typhoid carrying are justified only when associated with simultaneous disease of the gall-bladder, and success can be expected only when the typhoid bacilli have not taken up their habitat in the intestine.

A New Reaction for Bile Pigments in the Urine.—A. v. Torday and A. Klier in working with the stomach contents of a jaundiced patient found that the methyl-violet with which they were testing for free hydrochloric acid gave a red color instead of the usual blue. The urine of a jaundiced patient gave the same reaction. Investigating further, they found that various staining fluids gave similar reactions with the bile-stained urine. Pure bile pigments have not been studied. The method consists of adding one drop of a 1 per cent. solution of the dye to 15 c.c. of water, and to this 1 c.c. of urine. The results with various metachromatic basic and neutral stains were as follows: Methylene-blue gave a green color; Azure-blue, Giemsa's stain, methylene-green, thionin, toluidine-blue also turned green. A weak May-Grunwald solution bleached, a stronger one became greenish yellow. Dahlia-green and pyronin turned yellow, while kresyl-violet, methyl-violet, and methylene-blue-gentian-violet reacted with a violet-red color. Diazo positive urines also turn green with methylene-blue, but a much stronger solution of the stain is required than in the present case. The delicacy of these tests was found to be about twice as great as the iodine or the Gmelin test.

The Question of Lordosis and Albuminuria.—Bernard Vas replies to the monograph of Jehle, in which the latter stated that orthostatic albuminuria was always associated with lordosis. Vas studied 150 cases as to the association and found albuminuria and lordosis both occurring in fifteen cases (10 per cent.), albuminuria without lordosis in eleven cases (7.3 per cent.), and lordosis without albuminuria in nine cases (6 per cent.). From these findings he concludes that at the age of puberty orthostatic albuminuria occurred with or without lordosis with equal frequency, and that, on the contrary, lordosis could occur without albuminuria. These findings do not detract from the work of Jehle, who was the first to point out mechanical influences as the cause of albuminuria, and produced definite proof therefor. Among the various factors which may produce an albuminuria by interfering with the circulation in the kidney, lordosis plays an important part in many cases.

Treatment of Bullet Wounds of the Lungs.—Sandor discusses bullet wounds of the lungs, reports a case, and concludes that penetrating wounds of the lungs tend to heal without surgical interference, even after most threatening initial symptoms. For this reason general expectant treatment should be tried, with, however, all preparations made for operation. The dangers of wounds in the lung consist of hemorrhage and pressure from hemopneumothorax. The best and safest procedure in the treatment of either of these is to open the thorax at the proper time and stitch up the wound in the lung. In penetrating wounds surgical procedures may be carried out with impunity without any pneumatic apparatus. The indications for interference are changes for the worse in the general condition during expectant treatment.

Book Reviews.

Modern Medicine: Its Theory and Practice. In Original Contributions by American and Foreign Authors. Edited by William Osler, M.D., Regius Professor of Medicine in Oxford University, England; Honorary Professor of Medicine in the Johns Hopkins University, Baltimore; formerly Professor of Clinical Medicine in the University of Pennsylvania, Philadelphia, and of the Institutes of Medicine in McGill University, Montreal, Canada. Assisted by Thomas McCrae, M.D., Assistant Professor of Medicine and Clinical Therapeutics in the Johns Hopkins University, Baltimore; Fellow of the Royal College of Physicians, London. Volume VI. Diseases of the Urinary System—Diseases of the Ductless Glands—Diseases of Obscure Causation—Diseases of the Muscles—Vasomotor and Trophic Disorders—Life Insurance. Illustrated. Philadelphia and New York: Lea & Febiger, 1909.

The sixth volume of this system is in some respects at once the most interesting and the most practically useful of the series. While the diseases of the ductless glands and those that it is convenient to group under the comprehensive caption "Of Obscure Causation" are still for the most part the etiological riddles they have always been, still little by little through accumulated observations the acquisition of additional facts or the new interpretation of old ones a clearer insight into their nature is being gained, and at least some of the older theoretical misconceptions are being brushed away. The contributors to whom the various topics of this group have been allotted have shown much industry in sifting the voluminous literature concerned and equally commendable judgment in their critical discussions of the results so far available. As an example of this the article on the parathyroid glands may be cited, in which Dr. George Dock summarizes what has been learned in regard to the apparently very important functions of these structures whose significance has only lately come to be appreciated. But although these articles on the ductless glands and the maladies of uncertain etiology by Dr. George Dock, Dr. Warfield T. Longcope, Dr. Thomas McCrae, and Dr. Daniel J. McCarthy appeal to the imagination and suggest new possibilities in physiology and pathology, it is the first half of the volume that will most frequently be used by the average reader. In these three hundred and fifty pages the various diseases of the urinary system are very adequately discussed by Dr. John McCrae, Dr. A. E. Garrod, Dr. James B. Herrick, Dr. Thomas R. Brown, and Dr. Hugh Hampton Young. The diagnosis and treatment of nephritis form so important a part of the work of the general practitioner, and proper individualization in the management of the patients is so essential that these excellent presentations of modern practice can be commended most warmly to the attention of all medical men. A feature of much value is the thoroughness with which the dietetic regimen to be adopted under various conditions is discussed. The sections on diseases of the muscles are by Dr. Walter R. Steiner and Dr. Daniel J. McCarthy, and those on vasomotor and trophic disorders by Dr. William Osler and Dr. Charles P. Emerson. The volume closes with an instructive chapter on the medical aspects of life insurance by Dr. Charles Lyman Greene.

The Human Species. Considered from the standpoints of Comparative Anatomy, Physiology, Pathology, and Bacteriology. By Ludwig Hopf. Authorized English Edition. With 216 illustrations and 7 plates. New York, Bombay and Calcutta: Longmans, Green & Co., 1909.

The author of this interesting volume begins by discussing the distribution of mankind, man's ancestors, the structure and function of the different tissues; he then passes to the consideration of such questions as the origin of the mind, emotions and their expression, social customs, marriage, communism, modesty, shame, religion, etc. The diseases and parasites of man and animals are then considered; and there is an interesting chapter on self-help in animals. The volume is an attempt to show a comparison between the characteristics of man and those of the lower animals. The parallel thus drawn includes a study of comparative anatomy, physiology, psychology, and pathology. It will be found that some characters hitherto regarded as distinctively human are shared by the lower animals; and some others are proved to be peculiar to man, though he may not always be edified by his sole possession of the feature in question. The book is well written and entertaining, and is popular rather than profound

Studies on Immunity. By Robert Muir, M.A., M.D., Professor of Pathology, University of Glasgow. In collaboration with Carl H. Browning, M.D., Alexander R. Ferguson, M.D., and William B. M. Martin, M.B., Ch.B. London: Henry Frowde and Hodder & Stoughton, 1909.

This book is a record of original work on the subject of Immunity. The papers contained therein have all been published before, in the Proceedings of the Royal Society of London, and in various British medical and scientific journals. The papers thus incorporated in this volume are: On the action of hemolytic sera; on the combining properties of serum-complements and on complementoids; on chemical combination and toxic action as exemplified in hemolytic sera; on the hemolytic receptors of the red corpuscles; on the properties of anti-immune bodies and complementoids; on the action of complement as agglutinin; on the deviation of complement by a serum and its antiserum, and its relations to the precipitin test; on the combining properties of opsonins of normal serum; on the combining properties of the opsonin of an immune-serum; on the bactericidal action of normal serum; and, on the filtration of serum-complement. These have been but slightly altered from their original form, and are here arranged in such a way as to give a continuity to the whole. Workers on this subject will be glad to have these papers collected in a single volume.

Diseases of the Bones and Joints. Clinical Studies, by Joel E. Goldthwaite, M.D., Charles F. Painter, M.D., and Robert B. Osgood, M.D. Illustrated. Boston: D. C. Heath & Co., 1909.

Although the authors in their preface disclaim any intention of writing a book on orthopedic surgery, this book is written with a remarkable breadth of view, and in a most scientific manner, and sums up well the modern knowledge on this branch of medicine. There is a marked absence of "canned material" from the book, which is most refreshing, the pathology is up to date and unusually good, and the differential diagnosis of the various diseases, except that of Potts' disease, is excellent. The chapter on osteomyelitis is far better than that on the same subject in most surgical text-books, and those on tuberculosis of the smaller joints, the treatment of hip disease, and the technique of operations on tuberculous joints, are all very well done, also that on the pelvic articulations. The illustrations are numerous and clear, and made clearer by the notes that accompany them. It is evident throughout the book that the authors have studied their joints, and whenever it is possible they prove their case. The inclusion of a large number of histories is somewhat of a new departure. The faults of the work are minor ones; the English at times is involved, and at times incorrect, crinoline is called a cloth, a plaster dressing is called a cast, and the tendo Achillis is endowed with a sheath. These, however, do not affect the worth of the book. One may not agree with the authors in condemning the therapeutic test for bone syphilis, for when all is said and done, there are some cases that can be cleared up only in this way, and, in fact, while condemning it in one place, the authors recommend it in another. Too little is said of the treatment of tuberculous knee joint disease, and too little of tuberculosis of the fingers and toes, but these small faults are forgotten in admiration of the book as a whole.

Vaccine and Serum Therapy: Including also a Study of Infections, Theories of Immunity, Opsonins, and Opsonic Index. By Edwin Henry Schorer, B.S., M.D.; Assistant Professor of Parasitology and Hygiene, University of Missouri; formerly Assistant, Rockefeller Institute for Medical Research, New York City. St. Louis: C. V. Mosby Co., 1909.

An attempt is made in this work to bring up to date our knowledge concerning vaccines and immune sera. Sufficient space is given to the opsonins and opsonic index to render the exposition of this somewhat difficult subject fairly clear. The author argues wisely against indiscriminate and unscientific use of these methods of specific treatment in order that they may not unfortunately fall into the same premature disrepute which befell the application of tuberculin before its virtues, few though they be, were sufficiently exploited. The chapters of the volume deal with infections, immunity, modifications of Wright's determinations, nature of opsonins, and opsonic index in health and disease. The two final chapters discuss in detail vaccine therapy and serum therapy. It is important that every physician be well read upon this latest study of the application of the principles of immunity, even though it may yet be a long while before these principles will be usable by the general practitioner.

Society Reports.

AMERICAN LARYNGOLOGICAL ASSOCIATION.

Thirty-first Annual Congress, Held at the Harvard Medical School, Boston, Mass, May 31, June 1 and 2, 1909.

(Special Report to the MEDICAL RECORD.)

(*Concluded from page 539.*)

Tuesday, June 1—Second Day.

A New Method of Packing the Naris Designed to Prevent Postoperative Hemorrhage.—Dr. W. E. CASSELBERRY of Chicago described this method, which consisted in placing a rubber tent with a slightly bulbous end in the naris, pushing it far enough back to permit the bulbous end to project into the nasopharynx, and packing the tent with gauze with any of the usual packing instruments. He also presented a new model of the "quad" self-retaining speculum.

An Embryological Study of the Metaplasia of the Epithelium of the Tonsillar Crypts: A Contribution to the Origin of Lymphocytes.—Dr. GEORGE B. WOOD of Philadelphia read this paper, illustrated by lantern slides. He noted, first, that in the adult tonsil there were certain phenomena suggestive of the idea that the epitheloid cells of the crypts underwent a metamorphosis, the result of which was the formation of cells morphologically similar to lymphoid cells; second, that in the embryo the very earliest stages showed a peculiar activity of the epithelium, characterized by the separation of basal epithelial cells, rupture of the basement membrane and the presence in the epithelium and in the neighborhood around this epithelial center of cells morphologically similar to lymphocytes; third, that the increased growth of this epithelial tissue was attended by the deposition in its immediate neighborhood of more lymphoid cells; fourth, that transition cells between the typical epithelial cells and the lymphoid cell might be found not only in the epithelium, but in its immediate neighborhood. These transition cells were more easily studied, and were in greater number in the later stages than in the very beginning; fifth, that the polymorphonuclear cells were comparatively more abundant in the early stages than in the later. The appearance of polymorphonuclear cells in the early stages of the tonsil was difficult to explain. Their presence in the neighborhood and the tissues immediately surrounding them indicated that they were derived from the circulation. On the other hand, the transition types in very early stages in the epithelium would seem to show a common origin with the lymphocytes. They gradually disappeared as the tonsil developed, and this fact would lead one to think that they were not an essential part of the adult tonsil. It might be that the early change in the epithelium acted as a chemotactic power, attracting the polymorphonuclear cells. It might be argued that these latter, coming from the blood, gave rise to the lymphoid element, were it not for the peculiar metamorphosis of the cryptal epithelium. The origin and function of the polyleucocytes in the embryonic tonsillar tissue needed further study, but their mere presence did not, to Dr. Wood's mind, interfere with the epithelial origin of lymphocytes.

The Tonsil of the Infant, the Child, and the Adult.—Dr. HARRY A. BARNES of Boston read, by invitation, a short paper on this subject, illustrating it with lantern slides. He spoke of the commencement of tonsillar growth in the embryo and at birth. At the latter time we found the tonsil had very little lymphoid tissue. The epithelium of the crypts was essentially like that of the surface, except that at this period many of the crypts were still in the formative stage and showed either as solid epithelial buds or as buds in which the central cells had formed a core which was ready to be expelled. Between the fourth and sixth month of life the follicles, with their germinal centers, began to show distinctly, and with their appearance the lymphoid tissue becomes very active. Large numbers of lymphocytes invaded the cryptal epithelium and disintegrated its lower layers, so that they appeared as ragged strands of tissue extending from the surface of the crypt into the lymphoid tissue below. This disintegration was apparently by the pressure of numbers. At the same time the cryptal walls were pressed tightly together, so that their drainage became obstructed and the large numbers of lymphocytes passing through the epithelium into the crypt cavity were there retained and formed the cheesy masses so commonly found in the tonsils of childhood. After eighteen months of life we had conditions very favorable for infection, viz., poorly draining crypts containing these masses of cellular débris and a cryptic epithelium which could make but a poor defence if the other resisting powers of the patient were lower. At about puberty retrogressive changes commenced, drainage was more free, and the lymphoid tissue receded from the epithelium. This retrogression occurred only here and there. From the point of infection the conditions resembled those of the infant tonsil.

Dr. LEONARD W. WILLIAMS of Harvard University opened a discussion and spoke of the origin of the lymph cells and channels in various lower animals. He believed that the lymphocytes of the tonsil arose, like those of the lymph glands, in the mesenchyma.

Dr. H. L. SWAIN of New Haven referred to the early observations of Stoehr in Germany, when it was supposed that the destruction of epithelium of the tonsils was a real one, and that there was an absolute erosion of the cells, as shown in Dr. Barnes' pictures. Now, Dr. Wood would have us believe that the thinning out of this epithelium was more or less due to the active processes which the epithelia are undergoing in producing leucocytes. Dr. Swain believed that the tonsil was an active part of the lymphoid structure of the body, a lymph node with just as much importance, and no more, in the economy than any other lymph node except that it was the absorbent recipient of all matters coming into our lungs.

Dr. D. BRADEN KYLE of Philadelphia said that an epithelial cell in its transition stage was very much like a plant; one could not tell just whether it would turn out a beautiful flower or not. When the embryonic cell became fully grown we had no difficulty in classifying it. We could not have epithelium without connective tissue to support it. The former was, therefore, the dependent structure and got its nourishment from the latter. No one had yet proved that an epithelial cell grew from connective tissue.

A Case of Laryngeal Carcinoma Under Observation for Thirteen Years; Ultimate Laryngectomy.—Dr. HARMON SMITH of New York reported this case, which had originally come under the care of Dr. Cleitsmann, who had then reported it to the association. The patient had originally a distinctly whitish tumor of the larynx, the indications pointing to malignancy, although the earlier microscopic findings were "papilloma durum, probably malignant, perhaps cancerous." The patient was unwilling to have anything done, and disappeared from observation until 1907, when he came to Dr. Smith's clinic. A second specimen was reported as being pachyderma laryngis. After removal of each piece for examination the patient felt very much relieved. Some few months later the microscopist reported on another specimen to the effect that the growth was now assuming a malignant histological appearance. Finally the patient was prevailed upon to enter Roosevelt Hospital, and was operated on by Dr. George F. Brewer, the entire larynx being removed. A low tracheotomy was done ten days previously. Before the patient left the table a good-sized rubber tube was inserted into the stomach through the nose and the patient was fed in

this way. Recovery was uneventful. The larynx was filled with a sessile growth springing from nearly the entire right side of the internal structure, and apparently well limited posteriorly and anteriorly by the middle line. It had a white papillary and irregular surface. Sections showed under the microscope the appearance of flat-celled epithelioma, but other sections were very different. The microscopist observed that structure was not always a satisfactory guide for prognosis. The three points of interest in the case were, according to Dr. Smith, the following: (1) The long standing, slowly advancing malignancy of the tumor; (2) the almost positive belief in malignancy and yet the presence of sufficient doubt to make one refrain from radical operative measures (the reporter believed that in the early stages the tumor might have been removed by thyrotomy with a reasonable hope of nonrecurrence), and (3) the extremely small systematic manifestations for a malignant growth of such long standing.

Dr. D. Bryson Delavan of New York commented on the unreliability of the older statistics on the results of surgery in laryngeal cancer. He advised most strongly the setting apart of special surgeons for this class of patients.

Dr. Chevalier Jackson of Pittsburg heartily supported the position of the previous speaker as to statistics. Men said, "This patient is going to die of cancer of the larynx, and we might as well remove it for experience," and these operators rushed into print with their fatal case as a contribution to statistics. It was a crime to touch a case. We had mixed up our operable with our inoperable cases.

Dr. J. W. Gleitsmann of New York said that Sir Felix Semon had had a case similar to the one seen by Dr. Smith and himself, and had advised him at the time of the probably malignant character of the growth in the case now reported. This had now been actually confirmed.

Recent Cases of Sarcoma.—Dr. J. Price-Brown of Toronto reported cases that had recently come under observation, and referred to cases previously reported to the association. He offered the following conclusions: In sarcoma of the nose the usual site of origin was in the soft tissues, and not in the bony framework which supported them. The origin was usually in the form of a pedicle which rapidly became sessile. As this sarcomatous mass enlarged and pressed upon the surrounding mucosa, abrasions took place and they quickly became transformed into adhesions. These adhesions never attained the vitality and virility possessed by the pedicle. When once destroyed they were not likely to reform again. Recrudescence might, however, take place in the region of the pedicle, and in view of this contingency the regions should be kept under regular observation and control. Owing to the fact that in many cases of nasal sarcoma the affected cavity became entirely filled by the hemorrhagic growth, that its adhesions were extensive, and that it was impossible to locate them at time of examination, attempts at removal intranasally by the ordinary knife were inadvisable, but gradual and systematic dissection out by the cautery knife in suitable cases was a method which was always available and should be encouraged.

Dr. J. E. Logan of Kansas City related his experience with nasal sarcoma, citing cases he had already reported to the association. He agreed in the value of the cautery treatment in these conditions.

Dr. H. L. Swain of New Haven said he had developed a way in which it was possible to take out the lateral side of the nose and the whole sarcoma with it, with excellent results. He was not prepared to report any case now, but believed that it was possible to lift the nose and lay it back on the cheek and make a clean and complete removal.

Dr. W. L. Ballenger of Chicago reported one successful case of removal by the knife and forceps, and his patient was still living, six years after the operation. He would be somewhat doubtful as to the true sarcomatous nature of any pedicled growth. Nasal sarcoma was not as malignant as the same disease in other regions. This point should be remembered in comparing results with those in other areas. In the nasopharynx, however, sarcoma was a very malignant process.

Dr. F. C. Cobb of Boston called attention to the difficulty in distinguishing small, round cell collections caused by any degree of traumatism from a sarcomatous mass. With the spindle-celled or the melano-forms there was no difficulty.

Dr. O. T. Freer of Chicago said there was great difference in the rate of growth of round-celled growths undoubtedly sarcomatous.

Primary Cancer of the Trachea.—Dr. T. Passmore Berens of New York reported a case, and said that he had been able to find records of but thirty authentic cases. His patient was a man of fifty-five years of age, whose first symptom was a persistent cough, followed by dyspnea. Both vocal bands were reddened and thickened; beginning at the second tracheal ring was a grayish-pink, velvety mass running way round the trachea and diminishing its caliber to about one-third of its normal size. The patient was placed in the hospital and the trachea opened from the larynx to the sternal notch. The growth extended one inch below the latter point, was not adherent to the rings, and did not extend beyond the limits of the tube. The larynx was free from all malignant deposit. Owing to the extension of the process so deep down the trachea, exsection of the latter was out of the question, and the mass was curetted away apparently successfully, for the result of the curettage left apparently normal appearing tissue. The shock of the operation was considerable, though the amount of blood lost was trifling. The temperature was 101°; the patient did badly, and died of pulmonary edema and heart failure three weeks after the operation. Microscopical diagnosis, columnar epithelioma.

Dr. E. L. Shurly had seen a similar case diagnosed by the pathologist as angioma. The man died from hemorrhage following curettage through a tracheotomy wound.

Nasal Tuberculosis, Two Cases; One Involving Right Ethmoid Bone, with Recovery After Operation.—Dr. Otto T. Freer of Chicago reported these cases and gave a general description of tuberculous processes in the nose and of their relation to lupus. We might have the ulcer, tumor, diffuse infiltration, and formation of granulation areas. The author's first case was that of a girl of twenty years of age, on whom three operations were done. In the first the entire middle turbinate was removed, and also the tissue from the posterior border of the septum, where it assumed the form of an ulcerated tumor. The microscope showed it to contain abundant giant cells imbedded in fields of epitheloid cells, but no tubercles nor bacilli. Some weeks after there were evidences of recurrence, and further eradication was done, with but temporary relief. A third operation was done under half chloroform narcosis, and the right ethmoid region was thoroughly exenterated. Examination of the tissue removed showed typical miliary tubercle and some bacilli. The patient was nervous for some months after the last operation, being markedly asthenopic, but this symptom had disappeared and she was now in blooming health, nearly two years after operation. The second patient was a woman of fifty, presenting a grave variety of the infiltrative form. There was a bulging swelling on either side of the nasal bridge and a marked thickening of the septum, with ulcerations and irregular surface. The extent of infiltration rendered complete removal impossible, and the nostrils were simply freed. Microscopical examination showed epithelioid cells, lymphoid cells, polynuclear leucocytes, and giant cells. Tuberculin injections were given, but without perceptible benefit, and the patient passed out from under observation, so that the ultimate condition could not be learned.

Another Case of Nasal Tuberculosis.—Dr. W. Scott Renner of Buffalo, N. Y., reported this case. His patient was a healthy woman of twenty-eight years of age, whose nose was completely obstructed by a pyriform tumor occupying the position of the septum. A provisional diagnosis was made of sarcoma and a bit of the mass removed for examination, which showed it to be tuberculous, containing giant cells and bacilli. The lungs were normal, the heart not very strong, and there was a history of old glandular abscesses in the neck. The growth was removed piecemeal down to the cartilage, and later the anterior portion of the inferior turbinate, which was found to be infiltrated. The wound surfaces were treated with lactic acid and the edges cauterized with the electrocautery. Iodoform gauze was used as packing until healing occurred. The reporter said that he was not sure that this was a primary infection in the nose, in view of the old scar in the neck. The septum probably became involved first, and later the turbinate.

Dr. Emil Mayer of New York called attention to the difficulty in diagnosis in the early stages of these lesions. He did not believe that the term lupus should be dropped from our nomenclature. The size of the growth in the nose was no clue to its nature. This disease might advance to a late stage in the larynx with only trifling symptoms, or none at all.

Cavernous Sinus Thrombosis.—Dr. Lewis A. Coffin of New York reported the case of a woman of fifty-nine years of age, who presented typical evidences of acute frontal sinus disease, and was operated on, the complete Killian being done. No polypi or granulation tissue were found in the sinus, although the lining membrane was very thick from congestion, as was also that of the adjacent sinuses. The eye symptoms were relieved, but there developed a marked chemosis of the lower lid. A consultation was held and it was finally decided that there had been a thrombosis of the cavernous sinus, but it was also decided that the operation had been of the greatest benefit, as by reducing the edema about the tissues of the eye the sight of the patient had been saved, if not her life. To reduce the coagulability of the blood as well as to break up any existing thrombus or clot, lemonade was given freely. Recovery was without incident.

Teratoma of the Soft Palate.—Dr. Coffin also reported this case, his patient being a woman of sixty-six years of age, complaining of cough, at first ascribed to enlarged lingual veins. A small tumor was discovered behind and above the uvula, and of the shape of the latter, hanging free in the pharynx. It was thought to be papillomatous, but proved to be a teratoma. Dr. Coffin quoted Sarapin as saying that the mixed tumors of the palate formed a group by themselves pathologically, anatomically, and chemically; that they had a common origin with teratomata and teratoid growths, and that from a clinical point of view they were benign in character, easy to enucleate and not inclined to recur.

Dr. W. L. Ballenger did not think that the history given by Dr. Coffin presented the features of a cavernous sinus thrombosis. He was unable to tell in a case of his own whether the appearance of the skiagraph indicated suppuration in the sinuses or only a catarrhal condition. A mere clouding of the *x*-ray picture did not justify operation.

Bacteriology of the Normal Nose.—Dr. Frederic C. Cobb of Boston detailed the experience of himself and of Dr. E. W. Nagel in their experimentation along this line. His conclusions were as follows: (1) The principal source of bacteria in the normal nose was the vestibule. (2) Disinfection with peroxide and bichloride sterilized the vestibule for all organisms except the staphylococcus. (3) Disinfection by Harrington's solution would sterilize the vestibule of all germs (formula: corrosive sublimate, 2 grams; hydrochloric acid, 150 c.c.; alcohol, 70 per cent., 2,500 c.c). (4) The remaining cases showing bacteria might be due to some as yet undiscovered error in technique. (5) Cultures in pathological cases should be regarded as reliable only when the cot in the vestibule was sterile, and any form of staphylococcus should be treated with suspicion as the positive factor in any disease of the nose owing to the difficulty of eliminating its presence from the normal naris.

Dr. George B. Wood said that he would like to make Dr. Cobb believe that the interior of the nose, especially the posterior portion, was sterile in the normal individual. He believed that the normal sinuses were also sterile.

The Nose and Nasopharynx in Infants and Young Children.—Dr. J. M. Ingersoll of Cleveland gave a demonstration on this subject by means of charts. Concerning the development of adenoid tissue in the nasopharynx he said that, on account of the small oral cavity and shape of the nasopharynx in infants, a curette with a straight handle and its blade set at an angle of 55° to the handle would follow the posterior wall of the nasopharynx better and remove the hypertrophied tissue more completely than it would if the blade were more nearly perpendicular to the handle, as it was in many curettes. The bayonet blade of Fein was devised to permit greater latitude in the movement of the curette and thus allow its blade to follow the conformation of the nasopharynx. The width of the blade should be determined by the width of the nasopharynx. A curette 1.3 cm. wide, with a blade 1 cm. wide, was probably small enough for all infants. The shape of the nasopharynx in infants made it practically impossible to do a complete adenectomy with forceps.

The Action of the Respiratory Muscles in the Production of Voice.—Dr. G. Hudson Makuen of Philadelphia summarized his paper by saying that "the action of the respiratory muscles in voice production differed in some important respects from their action in passive breathing; while the function of the diaphragm was inspiratory in passive breathing, it must be expiratory in active or artistic breathing. Although this muscular diaphragm was generally classed among the involuntary muscles, its action, like that of so many other so-called voluntary muscles, might be brought entirely within the domain of the will. The proper use of the respiratory muscles for singing and speaking might be acquired by practice, and should be taught by the teachers of voice culture.

Dr. J. H. Lowman of Cleveland said he would like to ask Dr. Makuen if he had observed the Litten phenomenon during the breathing act. In many people this was not observable while the diaphragm moved distinctly.

Dr. J. Payson Clark asked if Dr. Makuen had used the fluoroscope during his observations.

Dr. Makuen said that experiments in this direction with the fluoroscope had thus far been very unsatisfactory, but hoped that the moving apparatus would be so perfected that it would become possible to make accurate demonstrations for teaching purposes.

The Choice of an Operation for the Correction of Obstructive Deviations of the Nasal Septum: A Personal Point of View.—Dr. W. L. Ballenger of Chicago said that, although he was an ardent partisan of the submucous resection, the technic was often difficult, the time for the operation long, and the difficulties many. The operation should be reserved for those cases which could not be corrected by other and simpler measures. In the choice of an operation certain fundamental facts should be remembered. Cartilage had a tendency to return to its former position. Bone, when fractured and placed in a new position, had but slight tendency to return to its former position. Roe's crushing operation might therefore be chosen in those cases in which the obstructive lesion was limited to the perpendicular plate of the ethmoid bone, and the author's operation might be practised when the obstruc-

tive lesion was limited to the vomer. Nonbeveled flaps which were not self-retaining, as in Asch's operation, required the prolonged use of some form of nasal splint for a period of from four to six weeks. So also did the Kyle operation. Any procedure which required the prolonged use of splints or tubes was not, in his (Ballenger's) opinion, justifiable. Nonbeveled flaps which were partially selfretaining, as in Sluder's operation, were utilizable in extreme angular deviations of childhood. Beveled flaps which were self-retaining were rational procedures for the correction of obstructive deviations limited to the cartilaginous septum (Watson, Gleason, Price-Brown operations). The submucous operation found its special field in compound deviations involving the cartilaginous and bony portions of the septum.

Dr. O. T. Freer of Chicago said in discussing this paper that fracturing operations were always uncertain, and he regarded the return to them as a retrogression.

Dr. J. O. Roe of Rochester was a believer in fracturing operations. The submucous operation was advantageous in cases with a marked septal thickening where we could thin out the cartilage and make a more ample breathing space, instead of cutting away the turbinate. When we had a thin, bony septum, simply bent out of line, it was absurd to go in and take out the bony framework. In all operations on the septum, no matter what one, for correcting cartilaginous deviations, the fracturing forceps as a supplement was indispensable.

Dr. Ballenger said, in closing, that it often required two hours for him to do a Freer operation, whereas in the method advocated by him the operation could be completed in twenty minutes. He would admit that the Freer operation would get the most perfect results if one took time enough and the patient had the endurance. Blindness and even death have followed the submucous operation, so also sinking in of the nose. He usually did a fracturing operation in young children or else the bevelling procedures, but saw no use in doing a submucous resection, as it took too much time.

Report of Fatal Case of Status Lymphaticus Occurring in a Patient Operated on for Tonsillar Hypertrophy Under Cocaine—Adrenal Infiltration.—Dr. Thomas J. Harris of New York reported this case. His patient was a Russian Jew, aged thirty, apparently in good health. One-sixtieth of strychnine sulphate was given by mouth after a fluid lunch. One-half hour later the tonsils were injected with about 1/12 gr. cocaine in salt solution, with 8 to 10 minims of adrenalin 1/1000. Immediately following a second injection (a first having been rejected), and the above figures representing the drug amount actually retained from both injections, the patient grew pale and vomited. Deep cyanosis followed. The operation was quickly concluded, when it was discovered that he was pulseless, while respiration was continued for some time. The symptoms were those of thymic death. Autopsy showed a markedly dilated right auricle and swollen right ventricle, enlarged axillary and groin glands, and a thymus weighing 18 grams. The cause of death was in all probability an overdilated right ventricle due to an enlarged thymus gland, with the cocaine and adrenalin acting as an exciting cause.

Dr. Thomas Hubbard added the history of one fatal case from adrenalin in his own practice. This drug had been used with great recklessness, and it was time to call a halt. He thought that 2 or 3 minims retained in the circulation was the maximum dose. His own patient was a healthy young man about to be operated on for septal trouble, and he was under chloroform and ether anesthesia. Every reflex appeared normal and respiration was perfect. He was given an injection of adrenalin for hemostasis, but part of it escaped into the stomach, and he received another, so that he probably got from 15 to 20 minims. During the second injection his heart fluttered; he gave twelve or thirteen respirations, and was dead. The adrenalin doubtless escaped into the circulation and caused the death.

Dr. H. L. Swain said that he had one case of enlarged thymus, and the external application of the adrenalin caused enough shrinkage to restore comfortable breathing. There was no incompatibility between the thymus and the drug. He thought that Dr. Hubbard was correct in assuming in these cases that the drug got into the circulation and caused immediate contraction of all the blood-vessels, sending the blood directly and forcibly back upon the heart.

Dr. J. O. Roe would hesitate to ascribe all the effect in this case of Dr. Harris to the adrenalin. Many patients had, however, a peculiar sensitiveness to cocaine.

Dr. Harris could not believe that the cocaine had had any deleterious effect in his case.

Nasal and Pharyngeal Conditions as Causative Factors in Aural Disease.—This session was held in joint meeting with the American Otological Society. Dr. George A. Leland of Boston, representing the Otological Society, said that many ear conditions which eventually threaten life had their origin in the nasopharynx. The reason for this might be found in the loss of protection normally provided for the safety and integrity of the conducting apparatus of the organ of hearing. A description was given of the arrangements of the Eustachian tube with reference to both anatomy and physiology, and the effect was mentioned of the influence of normal respiration on the movements of the drum membrane. Any interference with these functions would lead to improper ventilation and imperfect drainage of the middle ear. Hence, there would result depressed ear drum, adhesive catarrh effusions, inflammations, loss of hearing, and in less sthenic conditions the otitis media catarrhalis chronica of middle and later life, always amenable to treatment, but curable only in its earlier stages. In normal nasal respiration there was a rhythmic movement of air through the Eustachian tube, and freedom of ventilation through these channels was an essential of the integral ear. Earaches ought to be attended to, even though slight. Adenoids should be removed as soon as discovered. The fossa of Rosenmueller must be cleaned out. The effect of influenza, scarlet fever, and other poisons on the ear were well known. Under the author's direction 127 cases were examined in the scarlet fever wards of the Boston City Hospital with reference to the effect of the disease in causing enlargement of the nasopharyngeal lymphoid tissue. Forty-three were found without adenoids; of the eighty-four having them, seventy-two were without aural complications either past or present; of the twelve with aural complications, acute or chronic, all had adenoids, and of these five had them generally distributed, while in seven they were confined to the fossæ of Rosenmueller. The author said that children with earaches always had adenoids. Earache, it was true, might come from many areas outside of the nasopharynx, such as teeth, diseased tonsils, pharyngitis lateralis, etc., all by reflex. An enlarged middle turbinal might cause a feeling of fullness in the ear. There might be a low-tone tinnitus due to occlusion of the fossa of Rosenmueller, and, finally, vertigo might be due to an occluded nose.

Chronic Epipharyngeal Peridenitis in Adults.—Dr. James E. Logan of Kansas City described a condition found in many cases, some six of which were described in detail. It was an inflammation of the tissue in the neighborhood of the pharyngeal bursa which might occasion symptoms analagous to those of sphenoidal sinus inflammation. The inflammation seemed to involve not only the lymphoid tissue, but also the muscles, vessels, and connective tissue. Detailed microscopical findings in such cases were given by the author. The effect of such inflammations on the organs of hearing would be evident. If re-

peated attacks occurred, they left the patients especially liable to attacks of acute rhinitis and epidemic influenza. While this lymphoid tissue atrophied as age advanced, a very little of it might be sufficient to cause trouble. Diagnosis of the condition was easy. Prognosis was usually favorable, so far as the vault was concerned. The symptoms were those of repeated attacks of influenza, senations of fullness in the vault of the pharynx, desire to hawk and expectorate, etc. Treatment was total extirpation of the diseased tissue. The author's method of operating was described in full. He said that digital examination ought always to supplement that made by the mirror. In order to avoid hemorrhage he advised the preliminary stripping of the mass from its attachments to break up the continuity of the blood-vessels, and its removal with instruments two days later. The greatest abundance of the mass would generally be found in Rosenmueller's fossa.

The Importance of the Thorough Examination of the Nasopharynx in the Treatment of Ear Diseases.—

Dr. Francis R. Packard of Philadelphia read the final paper in the symposium. His conclusions were as follows: (1) In every case of middle ear disease which presented itself for treatment one of the most important measures to be employed was to make a thorough examination of the nasopharynx. (2) This examination should be made not only with the mirror, but also with the finger, not only before, but also after cleansing the nasopharynx. Thick mucus or other discharges might obscure the tissue changes. In children the nasopharynx should be cocainized through the nares previous to the digital examination. The same thing might be done with adults who would not tolerate the mirror. The disagreeable features of the procedure were no justification for its omission. (3) Although the presence of obvious growths, such as tumors or the existence of inflammatory condition in the nasopharynx had had the importance of their presence as a source of aural disease recognized for many years, the existence of adhesions in the nasopharynx as a cause of pathological conditions within the ear had been largely overlooked, chiefly because of the difficulty attendant upon the examination of the nasopharynx, which would lead to the discovery of their presence.

Dr. D. Braden Kyle of Philadelphia said that the natural course of procedure would be first the classification of causes. He referred to the various plans according to which this might be done, as mechanical, anatomical, pathological, etc. An anatomical cause might be a narrow naris or anatomical malformation. Atrophic rhinitis certainly predisposed to ear disease. All of the specific lesions, as tubercle, syphilis, etc., might be included in any class except that they were never physiological. The ear lesions were more common at puberty, and again at the menopause. Occupation, etc., was another factor to be considered, and such factors acted through the expending of their vicious influence on the respiratory tract and thence on the ear. He had seen the familiar soap bubble blowing of children cause ear trouble. The enlarged and imbedded tonsil obstructing the Eustachian tube might become an etiological factor in ear disease. It was very true that certain inflammatory conditions of the ear might exist without any pre-existing nasal lesion, or at least any discernable lesion at the time the aural lesion was discovered. In every case the first point for the practitioner to decide was this: Could this nasal causal factor be removed, and if so, had this nasal causal factor already produced permanent pathological lesions in the ear, or would the removal of the nasal obstruction remedy the ear lesion?

Dr. E. A. Crockett of Boston said that operations done on the nose for the relief of hearing were often done unadvisably and with promises to the patient as to results which could not possibly be made good. Otosclerosis was not a disease originating in the nasopharynx. Operations in the nose for it were not going to benefit the hearing. The same thing held true of the sinuses, nasal septum, anterior turbinates, etc. Care must be taken in adenoids to clear out the fossæ of Rosenmueller.

Dr. O. T. Freer of Chicago emphasized the necessity of thoroughness in the adenoid operation, and he advocated the use of his own perinasal forceps for this purpose. He had known hearing to return after septal operations and considered them justifiable in selected cases.

Dr. W. L. Ballenger of Chicago said that it was not alone the obstruction in the nose, but also and principally the associated inflammatory conditions, which gave the trouble to the hearing. The three main conditions to look out for were ethmoiditis and sphenoiditis, enlargement of the posterior ends of the middle turbinates and adenoids. Adults with chronic ear discharges often presented the remains of adenoids, and the same principles were applicable to them as to children.

Dr. G. L. Richards of Fall River advised the use of the thin rubber cap for the finger in digital examination of the nasopharynx. A special curette had been devised for the Rosenmueller's fossa.

Dr. F. P. Emerson of Boston called attention not alone to the adhesions around the lips of the Rosenmueller fossæ, but also to the amount of degenerated tissue in their depths. In such instances we might have unilateral deafness with low-pitched tinnitus. These cases could not be detected by the mirror, and we must use the finger. The physiological respiration of the palatine muscles produced a marked change, and undoubtedly the catheter had been much abused. Cases must be followed up, or else symptoms would return even after a thorough clearing out of the fossæ.

Dr. Emil Mayer of New York commended the use of the newly devised pharyngoscope in such cases.

Dr. Percy Fridenberg of New York said that the pharyngoscope could be borne by patients for ten minutes. It enabled us to study those various changes which take place in deglutition, gagging, coughing, etc., about the orifices of the Eustachian tubes. In this way we had learned that even in the presence of adenoids there might be a practically normal contraction of the soft palate and muscles around the tubes.

Dr. G. E. Shambaugh of Chicago said that doubtless we would all agree that many forms of ear disease, such as mucus accumulation, suppuration, etc., were improved by operation on the nasapharynx. But the cases which had been neglected and came to use in middle life with drum membrane covered with scar tissue, bound down, etc., did not benefit by operation. We must distinguish between middle ear diseases and anchylosis of the stapes. Obviously, if the labyrinth was involved, treatmeent of the middle ear would not benefit the hearing.

Dr. J. F. Barnhill of Indianapolis said that the breaking up of adhesions would not always relieve the difficulty. The tube might be pervious, although hearing was still defective. The breaking up of adhesions did good by exciting a certain amount of hemorrhage, and sometimes would relieve tinnitus. Moreover, there was a certain psychical element entering into the case. The continued attacks of nasopharyngitis were distinctly disastrous.

Dr. J. Payson Makuen of Philadelphia said that he was always in the habit of clearing out the vault with his finger before removing the adenoid growth, and in this way removed the latter more thoroughly.

Dr. J. Payson Clark of Boston said he could not accept the doctrine that every case presenting adenoid tissue in the nasopharynx called for surgical operation.

Dr. B. Alex Randall of Philadelphia emphasized the importance of massage. Adenoid operations would fail of benefit if there was a stuffed nose in front. He had never seen any brilliant results from clearing out the

Rosenmueller fossæ. Shrunken adenoid masses, although no longer obstructive, might often be removed with benefit. He had seen improvement in otosclerosis by treatment of the middle ear.

Drs. LELAND, PIERCE, LOGAN, and PACKARD closed the discussion.

The following papers were read by title: "Sloughing Fibroma of the Nasopharynx," by Dr. H. L. SWAIN of New Haven; "Report of Cases Illustrating Our Progress in the Surgical Treatment of Chronic Stenosis of the Larynx and Trachea," by Dr. JOHN R. WINSLOW of Baltimore.

At the executive sessions of the congress the following were elected to membership: Honorary Fellows (transferred from Corresponding Fellowship)—Prof. Dr. B. Fraenkel, Berlin, Germany; Sir Felix Semon, London, England.

Active Fellows—Dr. Albert C. Getchell of Worcester, Mass.; thesis, "Nasopharyngeal Fibromata," Dr. Burt R. Shurly of Detroit, Mich.; thesis, "An Investigation of Post-Operative Conditions, Five to Ten Years After Intubation," and Dr. Greenfield Sluder of St. Louis, Mo.; thesis, "The Anatomical and Clinical Relations of the Sphenopalatine (or Meckel's) Ganglion to the Nose and Its Accessory Sinuses."

Officers.—The following were elected for the ensuing year: *President*, Dr. James E. Logan of Kansas City, Mo.; *First Vice-President*, Dr. Cornelius G. Coakley of New York City; *Second Vice-President*, Dr. Harris P. Mosher of Boston, Mass.; *Secretary and Treasurer*, Dr. James E. Newcomb of 118 West Sixty-ninth Street, New York City (reelected); *Librarian*, Dr. Joseph H. Bryan of Washington, D. C.; *Member of Council* to serve for four years, Dr. Algernon Coolidge, Jr., of Boston, Mass. The meeting in 1910 will be at Washington, D. C., in connection with the Triennial Congress of American Physicians and Surgeons, May 3 and 4.

MEDICAL SOCIETY OF THE MISSOURI VALLEY.

Twenty-second Annual Meeting, Held at Council Bluffs, Iowa, September 9 and 10, 1909.

THE PRESIDENT, DR. C. B. HARDIN OF KANSAS CITY, MO., IN THE CHAIR.

Diagnosis and Treatment of Gastric Ulcer, with Especial Reference to the Lenhartz Diet.—Dr. LEROY CRUMMER of Omaha said the advantages of the Lenhartz treatment were, it was more comfortable for the patient, there was less loss of weight and nutrition, the period of return to normal diet was shorter, and the tendency to relapse was less. He had had the opportunity to carry out the Lenhartz treatment in eight cases of gastric ulcer, five of which were comparatively simple cases, and the treatment was successful without modifying any of the details. One case went through the treatment with seeming complete success, and left the hospital greatly improved in weight and strength, but died suddenly one month later with some acute abdominal trouble, probably perforative peritonitis. The other two cases, in addition to the clear ulcer condition, presented severe anemia and signs of pyloric obstruction. No operation was done in chronic ulcer till the patient had had the benefit of a careful trial with the Lenhartz treatment.

Dr. JOHN P. LORD said he recalled several cases of gastric ulcer in men who did well without having undergone surgical intervention. He spoke of this to emphasize the success which attended the expectant treatment of these cases. However, when an operation was indicated in gastric ulcer it was performed.

Dr. W. B. DEFFENBAUGH said in the medical treatment of gastric ulcer it was important to prescribe a diet which was free from irritating material. He said that the average diet contained many things that were imperfectly masticated; they passed over the inflamed area, or through the pylorus, and kept up a mechanical disturbance.

Dr. R. C. MOORE of Omaha said in his experience comparatively few cases presented the classical symptoms of gastric ulcer, but when he had one of these cases diet was the main thing to consider. He did not resort to feeding by the rectum. He kept the patient as quiet as possible, maintained the action of the different secretory organs as best he could, and placed the patient upon such treatment as could be digested. Milk was the main article of diet. When the case took on a surgical aspect, operation was considered, and, if thought necessary, performed.

Dr. W. L. Ross of Omaha said gastric troubles were functional, and not organic, and we should not be in too great haste in saying that this or that patient had ulcer of the stomach simply because he or she complained of pain. The whole symptomatology should be gone over in order to determine whether the cause was really located in the stomach or not.

Unrecognized Callstone Disease.—Dr. DANIEL MORTON of St. Joseph, Mo., emphasized the necessity for early recognition of gallstone disease. Courvoisier found seventy-two cases with gallstones present out of eighty-four cases of primary gall-bladder cancer. The inaugural symptoms of gallstone disease might be possibly best brought to the attention of the great body of general practitioners, therefore, by stating that cases of "indigestion," "biliousness," "neuralgia of the stomach," "gastralgia," and "autointoxication" were, in the majority of cases, in reality cholecystitis, and should be recognized and treated as such. The diagnosis could usually be confirmed by a physical examination of the gall-bladder and a search for the pressure pain points described. The gall-bladder, as an important factor in the causation of trouble in the organs adjacent, was rapidly assuming an increasingly important rôle.

Dr. JOHN MONROE BANISTER of Omaha said he would like to relate his experience in the Philippine Islands in reference to this line of work. In the United States we did not find conditions of extreme congestion of the liver and enlargement which we did in the tropics; consequently, a diagnosis of enlarged gall-bladder was easy. While in the Philippines he did a large amount of surgical work. They had a large number of cases of liver disease to treat, and in the number of cases on which they operated they never had a single case of disease of the gall-bladder. Frequently they thought they had, but in these cases the livers would be so enlarged from passive or active congestion as to fill the abdominal cavity. They made it a rule in suspicious cases to perform laparotomy as a routine measure, going in, getting the enlarged liver out of the way, exploring and examining the gall-bladder to see if there was anything the matter with it. They found the livers of these patients very much congested and enlarged. They made it a rule to aspirate the liver, and if they could not find an abscess they would draw off a good deal of blood, but these cases invariably did beautifully. He saw men who had been lying in bed for two or three weeks before they came to the hospital, and yet after this operation they began to get well and made rapid recoveries.

Dr. A. I. MCKINNON of Lincoln, Neb., said it was possible to have biliary or gallstone colic without the presence of gallstones. Gallstones were due ordinarily to infection. Cholecystitis frequently accompanied infectious diseases, and many times the trouble began in childhood, following some infectious disease. When they got an acute cholecystitis, for instance, complicated with pneumonia, they had jaundice, and as the growth of fibrous tissue replaced the exudate contraction took place and obstruction to the bile tracts occurred.

Dr. A. B. Somers of Omaha said the removal of the gallstones did not always relieve or cure the primary condition which still existed, and the patient should be taught to go to a physician when he got through with the surgeon, unless the surgeon was a physician.

Dr. W. F. Milroy of Omaha said he wanted to go one step further than the last speaker, and said that these patients should go to see a physician before they consulted a surgeon, as he was firmly convinced that most of these cases could be cured by medical treatment and required no operation whatever.

Splenectomy.—Dr. W. B. Deffenbaugh of St. Joseph, Mo., reported a case of traumatic rupture of the spleen, in which he resorted to splenectomy, with a successful result.

Dr. I. U. Parsons of Malvern, Iowa, said that several years ago a boy, ten years of age, fell across a washtub, striking himself in the region of the spleen. Several physicians saw the boy, but were unable to make a correct diagnosis. Two months after the injury a tumor developed in that region. The abdomen was opened and a large cyst of the spleen was found and drained. The boy recovered.

Dr. A. C. Stokes of Omaha said the spleen, according to German authority, had a physiological function. It had to do with infections in the production of immunity, or the swallowing up of infections. This was illustrated by the fact that so many patients who had infectious diseases had developed enlargement of the spleen. Embryologically, and from the standpoint of comparative anatomy, the spleen was more of a remnant than anything else, for in animals it was much larger in comparison with the body weight than it was in man. The blood supply was about the same.

Renal Tuberculosis.—Dr. F. Kreissl of Chicago read a paper on this subject, in which he discussed some diagnostic and therapeutic points in the management of this disease.

President's Address.—President Hardin offered some suggestions with reference to the future conduct and improvement of the society.

Cancer: A Constitutional Disease; Its Rational Treatment.—Dr. John E. Summers of Omaha delivered the address on surgery, selecting this subject. He referred to recent investigations concerning the medical and surgical treatment in cases of cancer of the genitalia, etc. In cancer of the uterus he first curetted thoroughly and dried carefully, then poured one-half ounce of acetone through a Ferguson speculum (patient in the Trendelenburg position), leaving this in for fifteen or twenty minutes; he then let the acetone run out and packed the cavity with gauze soaked in acetone. In rectal cancer he followed a like practice, only first introducing a tampon above the growth before using the acetone. He repeated the use of acetone two or three times a week in office practice, protecting the vulva with vaseline. The oozing was checked and the wound surface was covered with a thin, white film. The odor was remarkably reduced. The discharge was at first watery and then disappeared. The wound shrank and tended to heal. The health improved. The opsonic index was raised. Acetone bisulphite, a white powder, giving off pure acetone when dissolved, might be used in place of acetone. Besides escharotics, the *x*-ray and radium, which, when the cancer or sarcoma could be reached, tended to destroy or inhibit its growth, there were certain drugs of great value in the internal treatment of cancer. They were mostly of the alterative type, and usually best given hypodermically. Certain preparations of arsenic, mercury, and iron were to be commended. Iodine the speaker had not found so useful, but it had its friends. Having noted the fact that cancer never began primarily in bone, that sarcomas in which the bone element predominated were least malignant, it occurred to him that if in any way he could increase or overload the blood with lime it would be a rational therapeutic measure in the treatment of malignant disease as a post-operative measure of prophylaxis and as a remedial agent in conjunction with the hypodermic use of alteratives. So far he had reason to believe there was value in the remedy, and he hoped others would try it. He used the lactate of calcium given, to begin with, in a hypodermoclysis, 30 grains to 1 dram, in a pint of warm sterile water; later he continued the drug in 10 to 30 grain doses given by the stomach in hot water three times a day. It might be continued indefinitely, but at the beginning was apt to cause nausea. Thirty grains of the lactate in a pint of warm water might be given directly into a vein. In a bad, hopeless case of cancer of the throat he found that the lactate materially lessened the pain.

Advantage of Cholecystotomy in Draining the Deeper Biliary Tracts.—Dr. H. G. Welpton of Des Moines said this paper was suggested by a serious and unexpected complication that attended two cases of cholecystectomy in his practice. The cases were of the simple type, without adhesions, obstruction, or destructive changes. In one of his cases a large calculus formed with the hepatic duct above an acute angulation of the common duct. The angulation was due to an adhesion to the colon. In the other an acute exacerbation of a chronic pancreatitis came on at intervals obstructing the common duct. His cases were only partially relieved by removing the stone, by releasing the adhesions, and by drainage. Since reviewing the literature he limited cholecystectomy to these cases where either the gall-bladder or cystic duct had been contracted or obstructed, or where an irreparable damage from gangrene, infection, ulceration, perforation, or malignancy had occurred. He preferred to leave the gall-bladder, when possible, since excision did not remove the infection that was in the common and biliary ducts Gall-bladder drainage offered the best means of a complete cure of the infections of the deeper tracts as well as those of liver and pancreas. It also provided for a cholecystenterostomy in case of complete obstruction, and served as a guide to the deeper structures.

Surgical Suggestions for the Treatment of Chronic Appendicitis.—Dr. A. I. McKinnon of Lincoln, Neb., recommended that the incision be made high enough for examination of the upper abdomen and treatment of those parts which might be found involved. This incision could be made about the same as a gall-bladder incision, the lower end being even with the umbilicus, or at a point where most authorized incisions begin. Through such an opening the appendix could be easily pulled up and with the aid of the proper position of the patient the whole abdomen and pelvis would be open for examination. To further facilitate this exploration he advocated the sitting posture of the patient in this class of operation. He had used this method for several years with great success in handling the abdominal viscera.

Scientific Feeding.—Dr. Minda A. McLintock of Atchison, Kan., said that he enjoyed the best health, the keenest mentality, the highest physical powers, who could select for himself those articles of diet which would most nearly supply all the constituent parts of the body in natural proportions. To do this, first, food must contain all the nutritive elements the body requires. Second, only such foods must be combined at each meal as would produce chemical harmony in the stomach. Third, the food must be proportioned so that the body would not be overfed with certain elements of nutrition and underfed with others. No less important was the observance of natural laws or idiosyncrasies, namely, age, sex, temperament, environment, together with the season of the year, occupation, exercise, etc.

The Bacteriological Diagnosis of Epidemic Cerebro-spinal Meningitis.—Dr. S. R. Hopkins of Omaha presented a method of establishing a bacteriological diagnosis in this affection. He said that a Gram negative diplococcus occurred most often in the interior of the leucocytes of the spinal fluid. There were some six species of Gram negative diplococci with which it was possible to confuse the diplococcus of Weichselbaum, and chief among these were the diplococcus of gonorrhea and the so-called pseudomeningococcus. But for practical purposes, the identification of the meningococcus in the spinal fluid withdrawn by lumbar puncture from a patient presenting phenomena suggesting meningitis was a procedure fraught with little difficulty, and it was the only means of affirming a positive diagnosis. In staining by the method of Gram it was well to finish the staining process by flooding the slide with a one-fourth of one per cent solution of eosin in water, thus giving to the Gram negative bacteria a red color. In order to establish a certain bacteriological diagnosis one should in every instance resort to cultivation of the germs on artificial media.

The Objects of Mechanical and Surgical Treatment of Infantile Paralysis.—Dr. H. Winnett Orr of Lincoln, Neb., said that while in some cases the prime object of treatment was the correction of gross deformity, there were many cases in which a return of function might be obtained in muscles apparently completely paralyzed. The mechanical and surgical procedures which afforded the greatest opportunity for restoring the function of these muscles were discussed in detail.

Does the Present Conservatism in Pelvic Surgery Serve the Best Interest of the Patient?—Dr. Bernard A. McDermott of Omaha expressed himself as being opposed to conservatism or any plastic work in certain pelvic lesions such as a partially diseased tube or ovary. In the latter condition, the resection of a cystic or partially diseased ovary, as a routine procedure, was to be mentioned only to be condemned, as the cutting and plastic work necessary to such an operation usually produced more post-operative pain, tenderness, and general bad symptoms than would the original condition. He had seen this follow so many times that he was convinced it was better either to remove the entire ovary or to leave it. In uteri containing multiple fibroids, he thought it was better to do supravaginal hysterectomy than myomectomy.

Diagnosis and Treatment of Stricture.—Dr. A. C. Stokes, of Omaha, Neb., summarized the treatment of stricture of the urethra thus: "1. Alkalies, diluents, and rest are serviceable in most cases of stricture—sometimes indispensable if there be any serious complications. 2. All uncomplicated strictures, not highly irritable or resilient, should be treated by dilatation with soft instruments up to No. 15 French, and with conical steel sounds afterwards; reintroductions being made every third or fourth day. 3. Until well acquainted with the temper of a given stricture every sounding should be preceded by urotropin, followed by nitrate of silver. 4. Dilatation need rarely be carried beyond the caliber of the normal meatus. 5. Any stricture resisting dilatation must be cut. 6. For the pendulous urethra, internal urethrotomy. For the perineal urethra external urethrotomy or the combined operation. 7. In general, anterior stricture of the urethra is curable, deep stricture of the urethra incurable. 8. Impassable stricture without retention may usually be overcome with whalebone bougies by time, patience, and skill. If they finally proved impassable, the treatment is external perineal urethrotomy. 9. Retention is treated by hot baths, ether, opium, tincture of the sequichlorid of iron; failing these, by aspiration, or by external urethrotomy without a guide. 10. Traumatic stricture may be prevented by section at the time of injury. Once having shown itself, it usually requires excision for a cure. 11. Resilient and nodular strictures are best treated by excision. 12. Irritable strictures may often be cured without cutting."

The following papers were also read: "Cataract," by Dr. Flavel B. Tiffany, of Kansas City, Mo.; "Dementia," by Dr. Gershom H. Hill, of Des Moines, Ia.; "The Neglected Anus," by Dr. D. T. Quigley, of North Platte, Neb.; "Cancer of the Breast," by Dr. B. B. Davis, of Omaha; "Diseases of Metabolism as a Group," by Dr. Alfred C. Croftan, of Chicago.

Officers.—The following officers were elected for the ensuing year: *President*, Dr. A. B. Somers, of Omaha; *First Vice-President*, Dr. C. R. Woodson, of Saint Joseph, Mo.; *Second Vice-President*, Dr. Flavel B. Tiffany, of Kansas City, Mo.; *Secretary*, Dr. Charles Wood Fassett, of Saint Joseph, Mo., reelected; *Treasurer*, Dr. T. B. Lacey, of Council Bluffs, Iowa, reelected.

Omaha, Neb., was selected as the place for holding the semi-annual meeting in March, 1910.

MEDICAL SOCIETY OF THE COUNTY OF KINGS.

Stated Meeting, Held April 20, 1909.

Dr. Joshua M. Van Cott in the Chair.

A Brief Consideration of the Subject of Internal Secretions and Animal Therapy.—Dr. William Browning of Brooklyn read this paper. He said that the field of animal-extract therapy was distinctively a modern one. The general experience of the past had not been one to inspire confidence in the general utility of animal extracts. The subject had been so deeply tainted with charlatanism as to arouse the spirit of skepticism and criticism. Brown-Sequard was among the first to introduce animal extracts to therapy, when in June, 1889, he began to use testicular extract. Others mentioned in the brief historical review were Shaw, 1896; Abeli, who isolated nephritin; Takammie, who introduced adrenalin in 1901. The work of Sajous had been an elaborate study of animal-extract therapy. The thyroid was the ductless gland whose extracts had been among the first to establish its extensive rôle in therapeutics. Athyroidism or athyreosis, which was congenital absence or operative removal of the thyroid, resulted in cretinism, or myxedema, or cachexia thyreopriva (surgical), and in these conditions the administration of thyroid extract had proved not only valuable but also indispensable. It had been noted that pituitary hypertrophy followed thyroidectomy, which indicated some intimate connection between the two glands. Insufficiency of the thyroid was known as hypothyroidea or thyreoaplasia, and by some was considered as the fundamental factor in pachydermatoses, such as ichthyosis, scleroderma, psoriasis, pityriasis, etc., in some chronic arthritides, in sluggish and sleepy conditions, in lessened irritability of the sympathetics, in forms of infantile eclampsia, in thyroiditis, dysthyroidism, and thyroidotoxin effects. In lethargic states and narcolepsy the value of thyroid had been shown. Its use in melancholia was risky. Hyperthyroidism (hyperthyreosis) reduced weight in adults by increasing the nitrogen and phosphorus metabolism. It had been recognized by many as the cause of exophthalmic goiter. Nervous over-activity (insomnia, excitement, etc.) had been attributed to this cause, but was now attributed to hyperirritability of the symphathetics. The thyroid had a close relation to the genital sphere. There was enlargement of the thyroid at puberty, during menstruation, and in pregnancy. Sexual infantilism was usual in myxedema. Suppression of the menses was often followed by goiter, which disappeared on the return of the menses. After an early thyroidectomy there was an arrest in the development of the genitalia. Precocity was noted in some cases in which there was an early hyperactivity of the thyroid. The effects of administering thyroid (opotherapy) were as follows: It acted as a general depressant to the pulse and circulation

It relieved athyroidism and hypothyroidism. It increased weight in some backward children. After pertussis it had been noted that children grew very rapidly. This was supposed to be due to the large amount of thyroid secretion liberated into the blood as the result of the paroxysmal attacks of coughing, causing pressure on the thyroid. It had also been noted that the thyroid had certain undefined immunizing qualities. The preventive value of small doses of thyroid against mosquito bites was alluded to. Thyroid was recommended for obesity, for colloid goiter, and in puerperal eclampsia. There were also a number of antithyroid preparations for hyperthyroid conditions. That the parathyroid glandules had a rôle separate from that of the thyroid was proved by the postoperative tetany resulting from operative removal of the parathyroids. It was questionable whether the absence of the parathyroids had any relation to restlessness, insomnia, flushings, and numbness. Insufficiency of the parathyroids (hypoparathyreosis) was possibly associated in some causative manner with rickets, osteomalacia, and achondroplasia. It had a doubtful relationship to paralysis agitans. For tetany the subcutaneous injection of parathyroid nucleoprotein had been used. This was useless when given by mouth. Insufficiency of the pituitary body had been observed in dwarfism if the inadequacy had been congenital, in low arterial tension and fast pulse, and in sexual retardation in the young. Enlargement of the pituitary had been noted in gigantism, and in acromegaly, which was essentially a somatic overgrowth. It was also observed in amenorrhea, in atrophy of the genitals or sexual infantilism in the young, and in impotence. In castrated animals the pituitary underwent development. Enlargement of the pituitary sometimes produced mechanical effects through pressure upon adjacent cranial nerves. Opotherapy with pituitary gland caused arterial hypertension, had an antisecretin action on the pancreas, had a marked influence on the uterus, and increased the growth of many backward children. The absence, atrophy, aplasia, or fibrosis of the thymus and parathymus was normal after infancy or at puberty. Its premature subsidence was possibly accompanied by defective nutrition, such as marasmus or rickets. Where the thymus was absent, splenectomy was promptly fatal. Hypertrophy and persistence of the thymus (status thymicus) was responsible for thymic asthma, laryngismus stridulus, and glottic spasm in children, in which its action was solely mechanical. Thymic death occurred, but mostly in operations. Status lymphaticus and lymphatism were frequently associated with hypertrophied thymus. There was also a possible relationship between the latter and leucocythemia and leukemia. Hypertrophied thymus was common in Basedow's disease (Basedow-thymus). Tumor of the thymus was responsible for many cases of myasthenia gravis. Opotherapy with thymus was suggested as of possible though questionable value in rickets and muscular dystrophy. Insufficiency and hypoplasia of the adrenals were frequently at the basis of arterial hypotony, while bronze or Addison's disease was common in bilateral affections of the adrenals. Superadrenalism followed degeneration or atrophy of the ovaries or testicles. Solutions of adrenalin acted locally as vasoconstrictor, hemostatic, astringent, and myotic. There was some possible connection between the adrenal cortex and sexual development. Opotherapy with adrenal caused a digitalis effect on the heart and circulation, it possibly induced arteriosclerosis, and had an antisecretin action on the pancreas. The sexual glands also furnished internal secretions, and differed from the former class in having ducts. They included the testicles, ovaries, mammæ, prostate, and parotids. The absence through castration of the testicles, particularly of Leydig's or the interstitial cells, was responsible for eunuchism, if these structures were lost before puberty.

Medical Items.

Diagnosis of Syphilis with the Ultramicroscope.—Léon Bizard regards the ultramicroscope as a very valuable method of diagnosis in syphilitic lesions. It permits the physician in his office to differentiate between a syphilitic chancre and other infections. The examination may be made by any physician provided with a good microscope, immersion lens, Leitz condenser, and an adequate source of light. The examination of the organisms may be made living in distilled water or peptonized bouillon within a few minutes of being obtained, or dead for four or five days after withdrawal. The lesion is to be carefully cleansed with distilled water and cotton, and all crusts removed; it is scarified with a vaccinostyle and the drop mixed with distilled water on a slide, which is sealed with paraffine. The fluids that are most valuable for examination are the fluid from the chancre and moist lesions about the genitals. The organisms are abundant in the saliva. They are exceptionally found in erythematous secondary lesions of the skin; never in tertiary lesions or in the blood or body fluids. The diagnosis for the chancre is absolute.—*Journal de Médecine de Paris.*

Health Reports.—The following cases of and deaths from smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, Public Health and Marine-Hospital Service, during the week ended September 24, 1909:

		CASES.	DEATHS

ON THE DEVELOPMENT OF GASTRO-ENTEROLOGY IN AMERICA.*

BY JULIUS FRIEDENWALD, M.D.,

BALTIMORE, MD.

PROFESSOR OF GASTROENTEROLOGY, COLLEGE OF PHYSICIANS AND SURGEONS.

IN acknowledging my thanks to this association for the great honor conferred upon me in electing me its president, I feel that I cannot do better than to review in the brief period of time alloted me, the most important work achieved in America in the field of gastroenterology. In performing this task I do so not only with the view of bestowing just praise upon those who have contributed most to our knowledge of the subject, but at the same time to point to the many problems which still confront us, and to which it behooves us as workers in this field to still further direct our attention.

In glancing back to the beginning of the nineteenth century we find some epoch-making discoveries in this branch of medicine. There can be no question, as I shall presently show, but that the invention of the very instrument by means of which so much knowledge has been gained in the field of gastroenterology—I refer to the stomach tube—must be attributed to the ingenuity of an American physician.

Two English surgeons, Jukes and Bush, are, however, very generally given credit for this invention, based upon an article by Jukes in the *London Medical Repository*, 1822, under the title: "Description of an Apparatus for Removing Poisons from the Stomach, invented by Mr. Jukes, Surgeon."

In looking over some early volumes of *The Eclectic Repertory* several years ago, I was rewarded by the discovery of a paper in Vol. III, 1812, entitled, "Account of a New Mode of Extracting Poisonous Substances from the Stomach," by Philip S. Physick, M.D., Professor of Surgery in the University of Pennsylvania. Physick reports two cases of whooping cough in twins, three months old, to whom the mother had administered laudanum for restlessness, with serious consequences. The laudanum bottle had been left uncorked for several weeks and the fluid had evaporated from one ounce to scarcely a drop. This served for a dose for one, and two drops of water shaken with the residue was given the other child. Symptoms of opium poisoning rapidly developed, and Physick was hastily summoned. He found both children in such a state that swallowing was impossible and the idea of injecting an emetic into their stomachs occurred to him. Putting this idea into effect he passed a large flexible catheter for a stomach tube, and with a pewter syringe injected ipecac and warm water. The stomach contents were withdrawn and the process repeated using warm water alone; both patients received the stomach washing, and one recovered.

This first application of a tube and syringe for washing poisonous materials from the stomach took place about twelve years before its publication (that is, in 1800), and in the meantime Physick had been recommending the procedure in his lectures. Upon his advice his nephew Dorsey had had stomach tubes made in Paris as early as 1803, and had made use of them in cases of poisoning. Since the work of Jukes did not appear until 1823 there can, therefore, be no doubt that Physick was the inventor of the stomach tube and the first to make use of this apparatus.

We can next point with pride to the "Pioneer American Physiologist," Beaumont, whose remarkable experiments upon Alexis St. Martin, published in 1823, are epoch making. This work is so familiar to you that it is hardly necessary to refer to it in detail. The results of these observations, as summarized by Osler, are as follows:

"First, the accuracy and completeness of description of the gastric juice itself. Second, the confirmation of the observation of Trout that the important acid of the gastric juice was the muriatic or hydrochloric. Third, the recognition of the fact that the essential elements of the gastric juice and the mucus were separate secretions. Fourth, the establishment, by direct observation, of the profound influence on the secretion of the gastric juice and on digestion of mental disturbances. Fifth, a more accurate and fuller comparative study of the digestion in the stomach with digestion outside the body. Sixth, the refutation of many erroneous opinions relating to gastric digestion and the establishment of a number of minor points of great importance, such as, for instance, the rapid disappearance of water from the stomach, through the pylorus—a point brought out by recent experiments but insisted on and amply proven by Beaumont. Seventh, the first comprehensive and thorough study of the motions of the stomach, observations, on which, indeed, are based the most of our present knowledge. And last, a study of the digestibility of the different articles of diet in the stomach, which remains to-day one of the most important contributions ever made to practical dietetics."

The essayist has well said: "Beaumont is the pioneer physiologist of this country, the first to make an important and enduring contribution to this science. His work remains a model of patient persevering investigation, experiment and research, and the highest praise we can give him is to say that he lived up to and fulfilled the ideals which he set out and which he expressed when he said, 'Truth, like beauty when unadorned is adorned most, and

*President's address, read at the twelfth annual meeting of the American Gastro-Enterological Association at Atlantic City, June 7, 1909.

in prosecuting these experiments and inquiries I believe I have been guided by its light.'"

It is interesting to note here that another American had investigated the physiology of digestion thirty years before the publication of Beaumont's work. This fact was brought to light in a recent article by Prof. L. B. Mendel, who refers to a thesis, entitled, "An Experimental Inquiry into the Principles of Nutrition, and the Digestive Process," submitted to the faculty of the University of Pennsylvania in 1803, by Young, a Marylander. This investigator introduced small animals into the stomachs of frogs, observing from time to time the progress of digestion upon these tissues. In addition he removed the gastric secretion from animals and utilized it for test-tube experiments. He investigated the digestion of vegetables and bread stuffs by introducing these foods, ingeniously enclosed in linen bags, into the frog's stomach, and making observations on the digestive changes at the end of varying periods. He disproved the occurrence of an acid fermentation by the aid of a friend, Mr. Mitchell, who, "being in good health and having the power to ruminate, was experimented upon." Young's description of the digestive process is complete and remarkably accurate, and well worthy of your hearing but the time at my disposal necessitates its omission.

It is interesting to glance at some of the contributions to gastroenterology published in the early part of the nineteenth century. These are largely of a clinical character and consist mainly of reports of interesting cases. Thus Dr. William Shaw, in *The American Medical Recorder* in 1818, records an unusual case of abdominal surgery. He was called to see a woman, who, as he remarks, had been shockingly gored in the abdomen by a cow. There was present a wound through the abdominal wall sixteen inches long. In order to ascertain the extent of the injury to the internal organs, he introduced his hand and fore-arm, upon the withdrawal of which a considerable amount of fat followed. This he was obliged to excise. The abdominal wound was sutured and the patient made a rapid recovery. The result obtained in this case could hardly be surpassed by the achievements of modern surgery.

Dr. Archer of Maryland had already recorded a similar case of early surgery occurring at the end of the eighteenth century. In a difficulty with a negro the patient had received a wound in the right side of the chest from a large knife which entered the cartilages of the false ribs and penetrated the stomach. The wound was nearly three inches long and was situated about two inches below the level of the ensiform cartilage. The stomach opening was more than two inches long. The contents of the stomach were partially discharged through the wound, some escaping into the peritoneal cavity. The wound was stitched by an old sailor with an awl, needle, and thread. Recovery was rapid and uneventful.

Equally interesting is a case of cancer of the pylorus reported by Dr. John Eberle in *The Medical Recorder* in 1818. The patient, a man of fifty-five, had had a carcinoma of the lip removed by Dr. Physick the year before. The symptoms were frequent vomiting of a dark-colored fluid, intolerable, burning sensations in the stomach noticed especially after the administration of drugs, and chocolate-colored stools. On examination an irregular indurated mass was palpable in the lower part of the epigastrium. The patient died and at autopsy the pylorus was found almost completely occulated by a scirrhous growth involving it, weighing one pound and two ounces. The tumor was similar in appearance and structure to the one removed from the lip.

A very instructive paper by Dr. John Revere of Baltimore, on "Some Cases and Observations on Dyspepsia," appeared in *The Medical Recorder* in 1821. The author outlines in detail the treatment of dyspepsia and illustrates his subject by the report of five cases. The importance of diet, massage, and exercise in the treatment of this condition is emphasized, and certain rules in this regard are submitted which may even to-day be read with profit. He says diet "should consist of food readily soluble in the gastric juice and should be exhibited in moderate quantities at regular intervals. The stomach is capable of performing a certain amount of duty with ease to itself and benefit to the general system; like the other organs, too, if it be taxed beyond this point it either acquits itself imperfectly or entirely fails."

For constipation he recommends horseback riding, which produces a wholesome agitation of the body, eating of small quantities of ripe fruit in the forenoon, regularity in going to stool, and the occasional dose of a mild laxative or enema. This publication indicates that even as early as 1821 diet, massage, and exercise were recognized as important factors in the treatment of chronic gastric and intestinal disorders.

In 1821, Dr. John C. Cheesman reported "A Singular Case of Ulcerated Stomach Unattended During Life by any Symptom of Disease of the Organ." The patient, a man sixty years old, was suddenly seized with a violent pain in the epigastrium extending to the umbilicus. Death occurred and at autopsy a perforated ulcer three inches in diameter, with ragged elevated edges, was found on the anterior wall of the stomach.

Dr. Robert Archer, in the second volume of *The American Recorder* (1824) records a case of "Intestinal Polypus," where for fifteen years the patient had suffered with acute attacks of pain in the lumbar region which were relieved by evacuation of the bowels. Finally during one of these attacks a rather drastic cathartic was prescribed and, in the evacuations resulting, a polyp two and a half inches in diameter was passed.

During the first half of the nineteenth century a number of interesting articles appeared containing observations upon a condition known as milk sickness or sick stomach, an epidemic disease only occurring West of the Allegheny Mountains, especially in the States of Indiana and Illinois, and presenting symptoms largely of a gastro-intestinal character. A very complete and vivid description of this condition is given by Graff in *The American Journal of Medical Sciences* in 1840. The chief symptoms of the disease in man are, breifly, loss of appetite followed by pain and excessive irritation of the stomach, obstinate constipation, fever, intense burning in the epigastrium, persistent vomiting, intense abdominal pain, and headache; the patient becomes restless and irritable and the mind confused. After six or eight days diarrhea sets in, with marked prostration and convulsions. If recovery takes place the patient does not retain the slightest recollection of anything occurring during his illness. This disease became rare after the clearing of the forests and it has been recently demonstrated by

the Bureau of Plant Industry that the cause of the disease is a poisonous variety of loco weed. Jameson, in 1825, reported a case of stricture of the esophagus, illustrating the employment of a very ingenious set of instruments for the relief of this affection. The author relates the clinical history of a woman forty years old, who had experienced difficulty in swallowing solids for two years, and dated the inception of the trouble to a choking spell after swallowing a piece of beef. The condition had gradually grown worse, and the patient seemed threatened with starvation. Jameson introduced probangs and bougies but was unable to pass a stricture which appeared to be located just below the pharynx. After many attempts he succeeded in passing a small probe and then he was able to introduce well through the stricture a probe armed with a piece of dried cat's intestine which was forcibly injected with water by means of a syringe. The water was replaced by mercury, the weight of which served to dilate the parts to a slight degree. He then began the use of sliding probangs, employing No. 1 (see figure) at first. By passing the probe through the stricture for about two inches and introducing the wire into the opening in the outer end, the wire and probang were brought together and passed through the stricture. This procedure was repeated several times a day. As the passage became easier probangs of gradually increasing size (Nos. 2, 3, 4 and finally 5) were substituted. Recovery was complete.

In connection with this case it is interesting to note the description of "A New Oesophagus Forceps," by Weaver of Detroit, in 1834, published in *The American Journal of Medical Sciences*. This instrument was devised to remove foreign bodies such as pins, needles, and sharp pieces of bone from the esophagus.

Diaphragmatic hernia, which has elicited so much interest in recent years, was well described by Edward Cornell in *The Medical Recorder*, in 1825, in an article entitled, "A Case of Escape of All the Intestines Through a Hole in the Diaphragm into the Right Side of the Thorax." The patient was a child ten months old. The symptoms first manifested were slight dyspnea and cough at seven weeks of age, progressing shortly after into choking spells, marked dyspnea and cyanosis. On examination, the right side of the chest appeared larger, on palpation it was hyperresonant, and an unusual sound was noted on ausculatation. The abdomen was empty and flaccid. Death finally ensued, and at autopsy the right side of the thorax was found filled with intestines. In the diaphragm on the right side there was an opening two and a half inches in circumference admitting all of the small intestine and the large intestine except the rectum. Between the diaphragm and the intestines were numerous fibrous adhesions. The right lung was compressed to one third its normal size.

In *The New York Medical and Physical Journal* of July, 1826, Professor Holmes reports an interesting case of an infant in whom the esophagus and trachea communicated. It lived ten days and whenever applied to the breast drew the nipple in the usual manner, but was seized at once with symptoms of suffocation, which were only relieved by vomiting the milk it had swallowed.

In a very interesting manner, Dr. W. E. Horner enters into an "Inquiry into the Healthy and Diseased Appearance of the Stomach and Intestines," in the first volume of *The American Journal of Medical Sciences*, in 1827. The naked eye appearance of the mucous membrane in these organs in cases of congestion and acute and chronic inflammations is described in a most thorough manner, indicating a clear conception of the morbid anatomy in these conditions.

Dr. Henry Dickson, in an article on "Observations on the Black Vomit," published in *The Philadelphia Journal of Medical Sciences*, August, 1827, gives an excellent description of this condition, with particular reference to symptomatology and pathology, based upon a number of personal observations. The writer advanced the idea that the black vomit was due, not to a gangrenous condition of the mucous membrane of the stomach, a view very generally held, but to a peculiar secretion from the vessels of the stomach. "Observations on Dysentery," is the title of a paper appearing in the *American Medical Recorder*, in 1828, by Wm. Horten of Goshen, N. Y. Both the sporadic and epidemic forms of dysentery are considered, with detailed description of symptoms and treatment. The thorough evacuation of the bowels by means of a suitable cathartic is strongly advised and the doctrine that dysentery is not a local but a constitutional disease and should be treated on this principle, is enunciated.

Edmond W. Roberts reports a case of "Scirrhus of the Stomach" in the *American Medical Recorder*, 1828, in which he describes the clinical history and gives the postmortem findings. The symptoms were pain, eructations and vomiting of a coffee-ground material. On examination a mass of considerable size was palpable in the epigastrium. On postmortem examination the pylorus was found involved in a hard growth which markedly constricted the lumen of the bowel.

In *The American Journal of Medical Sciences*, of 1830, Dr. L. Rawson presented an interesting case of "Perforation of the Stomach," resulting from ulceration. The patient, a man of thirty-six years, was suddenly siezed, while at work, with intense epigastric pain, vomiting, and collapse. He had suffered with indigestion for about a year. A diagnosis of rupture of the stomach was made. Death occurred in twenty-seven hours, and at autopsy the contents of the stomach were found in the abdominal cavity; and on the anterior surface of the stomach, midway between the pylorus and cardia, a perforation, seven-eighths of an inch in diameter, was observed. The opening presented thick ulcerated edges surrounded by adhesions, clearly a perforated ulcer.

An early case of intussusception was recorded by Samuel Jackson in *The American Journal of Medical Sciences* in 1833. The patient was suddenly stricken with violent pains in the right lumbar, iliac, and hypochondriac regions, accompanied by vomiting of a greenish fluid. Constipation was marked; there was no elevation of temperature. Death ensued, and at autopsy the ileum was found inverted through the iliocecal valve, forming with the cecum a firm cylindrical body.

In a paper entitled, "Gastritis Superinduced," Charlton, in 1834, calls attention to the fact that while medicinal agents are intended to relieve disease that, frequently, when of a drastic character, they may instead act as causative factors. He reports a number of cases illustrating this point, one in which tarter emetic, given in a mild febrile disorder, induced an attack of gastritis. He called attention, even at this early period, to the fact that

rapid recovery may be brought about by rest and diet alone, a principle which has been more actively promulgated in recent years. Several excellent contributions to the subject of digestive disorders were made by Chapman between 1833 and 1841. Of special interest are monographs on dyspepsia and diseases of the intestines, and a lecture on cholera morbus delivered before the students of the University of Pennsylvania. In his discussion of dietetics in connection with dyspepsia, his views are largely those we hold to-day. The monograph on inflammation of the intestines contains a thorough description of acute and chronic enteritis with treatment. His conception of the pathology of these conditions was rather vague, but the chapter on treatment may even now, some seventy years later, be read with profit.

A very interesting case of hepatic abscess in which tapping was done was reported by Dr. W. L. Horner in 1834. The description clearly indicates that the case must have been one of amebic dysentery with abscess of the liver, which, of course, was not recognized as such at that time. Two months after a recurring attack of dysentery, the patient began to suffer with severe pain in the epigastric and right hypochondriac regions, associated with chills, and irregular fever; the liver was enlarged and after some days fluctuation could be made out. The patient lost ground rapidly and evacuation of the abscess was deemed imperative. The liver was exposed and five gallons of pus evacuated through a trocar. Relief was immediate. The trocar was left in place fifty-four hours and then a catheter was substituted for drainage. There was a constant free discharge of pus. On the second day abdominal tympany, hiccough, and pain set in and the patient died on the fifth day.

George Sumner reports in 1837, a case of cancer of the stomach in a man, who, for years, had been in the habit of swallowing foreign bodies. At one time upon a wager he swallowed a live snake which he afterward vomited. The writer suggests a causative relationship between these irritants and the appearance of a cancer in later life.

In 1841, Flint discussed very completely the various psychic phenomena often associated with dyspepsia; indefinite sensations of fear and apprehension; worry and depression over imaginary diseases from which the dyspeptic has absolutely no hope of recovery; inaptitude to both mental and physical exertion; absence of volition; difficulty of mental concentration, etc.

Flint also points out the existence of dyspepsia secondary to certain nervous or mental states—a condition which we now recognize as nervous dyspepsia.

John Watson contributed in 1844, a very instructive article entitled, "Practical Observations on Organic Obstruction of the Esophagus."

A case of tuberculous ulcer and stricture is described, in which esophagotomy was performed for the relief of the aphagia which had developed. A tube introduced through the wound afforded a means for introducing nourishment, but perforation between the esophagus and trachea took place, necessitating an immediate tracheotomy, and death from pneumonia occurred a few days later.

Another case of esophageal stricture was reported by Cummins in 1851. The patient was a child with a stricture due to swallowing caustic potash; even liquids were swallowed with difficulty. After futile attempts at dilatation with gum-elastic bougies, a small ball probe was finally passed. This was followed by probes of gradually increasing size. Temporary relief was afforded but symptoms soon recurred, and in attempting to force a passage with a ball probe of considerable stiffness, the esophagus was ruptured. The child died one day later.

We find an anticipation of later discoveries upon the relationship of bacteria and parasites and their toxins to disease in an article by Charles Frick in 1851, on "The Pathology of Epidemic Dysentery." The writer suggestively remarks: "If we consider attentively the collection of symptoms, and note the great mortality attendant upon them, even in the first few days, we cannot but be struck with the fact that the cause of death is not sufficiently evident; that the severity of the local disturbance is inadequate to produce a fatal result, and the idea constantly intrudes itself, that some morbid poison in addition to the local disease has an agency in producing the extreme prostration and subsequent fatal termination."

It was about the middle of the nineteenth century that a new era dawned in American medicine, when experimental investigation began to forge into prominence. Up to this time the work in gastroenterology had been largely of a clinical character, but the work of Beaumont on the physiology of digestion, which had been heralded abroad, had sown the seed of enthusiasm and zeal for research on this side. Jackson, in 1854, confirmed Bernard's observations concerning the digestion of fats, which had been disputed by Bidder and Schmidt, and Lehman and Frericks.

John Dalton about this time described fully the nature and function of the gastric juice, based upon a series of experimental studes; and in 1857 this author contributed a most admirable and instructive article on "The Constitution and Physiology of the Bile." He presents in detail his researches upon the comparative study of bile in different animals with particular attention to its chemistry. He demonstrated that bile passes into the intestines of carnivorous animals for at least twelve hours after meals, and that it is discharged most abundantly immediately after feeding.

In 1860, Flint called attention to the relationship between anemia and atrophy of the gastric tubules, and expressed the belief that some cases of obscure and profound anemia are dependent upon degeneration and atrophy of the glands of the stomach. It was twenty-six years later that the well-known paper of Henry and Osler on "Atrophy of the Stomach with the Clinical Features of Progressive Pernicious Anemia," was published, in which it was again pointed out that a primary atrophy of the gastric mucous membrane might occur, and the theory advanced that certain cases of progressive pernicious anemia depended upon profound alterations in the gastric tubules.

DaCosta, in 1867, and Robert Harris, in 1872, directed attention to the difficulty in diagnosis in certain cases of abdominal tumors on account of the obscurity of the symptoms. Case reports with autopsy findings illustrating this contention are submitted.

The clinical history and treatment of membranous enteritis are described by DaCosta in 1871, and Findless in 1875. They both recognize the frequent occurrence of this affection in nervous and hysterical individuals, its very protracted course, and the importance of rectal irrigation as a routine course of treatment.

Of great importance is the classic work of J. J. Woodward on "Diarrhea and Dysentery," published in 1879 in "The Medical and Surgical History of the War of the Rebellion." In this comprehensive volume of 869 pages, Woodward gives a complete statistical report of the cases of diarrhea and dysentery occurring during the war, descriptions of the fatal cases, an account of the pathological changes observed, and a discussion of the treatment of these affections. There can be but little question that this extraordinary volume may be classed as one of the greatest works published in the field of gastroenterology in America.

Reginald Fitz reported in 1877 a remarkable case of rupture of the healthy esophagus. The patient had become strangled with an article of food which lodged in his throat. After an hour's discomfort the food was ejected with a moderate amount of blood. The patient became greatly exhausted and finally succumbed; at the autopsy a rupture of the esophagus was revealed.

To Meltzer is due the credit of first investigating the peristaltic movements of the esophagus. Associated with Kaonecker in 1883, he demonstrated the incorrectness of the view, previously maintained, that the food is forced into the esophagus by the contraction of the pharyngeal muscles and showed that the contraction of the mylohyoid muscle shoots the bolus through the entire esophagus in the case of liquids or very soft food. When the food is semisolid or solid, however, Cannon and Moser demonstrated by means of the *x*-ray that the passage through the esophagus is accompanied by peristaltic contraction of its muscles. It was Meltzer, too, who in 1833 first noted the importance of the sounds of deglutition.

A work which did much to develop the entire field of gastroenterology in this country is the excellent and comprehensive production of Welch in Pepper's System of Medicine, 1885, comprising contributions on ulcer and cancer of the stomach and dilatation. This work is in many respects the most exhaustive ever published on these subjects. The entire literature is reviewed and new statistics prepared from a large series of cases, the whole forming a complete monograph, which has helped to form the foundation for the study of these conditions according to modern methods.

Great credit is due Reginald Fitz for his masterly and epoch-making work on acute pancreatitis, published in 1889, in which he treats of the etiology and symptomatology of this affection and its relationship to other diseases. He discusses the significance of pancreatic hemorrhage, the cause of sudden death in acute pancreatitis, and the relationship of acute pancreatitis to fat necrosis.

It was but little more than a decade later that Opie pointed out the frequent association of cholelithiasis and disease of the pancreas. He says: "A small calculus may lodge at the orifice of the diverticulum of Vater and by occluding it convert the common bile duct and the duct of Wirsung into a continuous channel causing the penetration of bile into the pancreas and subsequent hemorrhagic pancreatitis; while a larger calculus present in the diverticulum or in the common bile duct slightly above its juncture with the pancreatic duct may temporarily or permanently compress the latter and produce chronic inflammatory changes." Opie further studied the changes in the pancreas in diabetes and found in a certain proportion definite changes in the Islands of Langerhans.

In 1869, Alfred L. Haskins collected the histories of thirty-five cases of marked dilatation of the stomach, with a complete discussion of the etiology, symptoms, diagnosis, prognosis, and treatment of this affection.

W. T. Mayo, in 1887, was the first to direct attention to the affection of "Acquired Diverticulitis of the Large Intestine." He emphasized the fact that the term diverticulitis should be applied only to cases in which there is an acute inflammation of the mucosa within the diverticulum, while a chronic inflammation of the subserosa around the diverticulum should be designated peridiverticulitis. The acute ulcerative type is characterized by a primary inflammation of the mucosa of bacterial origin while the chronic inflammatory type is produced by a leakage of toxins or bacteria through the diverticular wall producing a reaction of the peritoneum. The former causes no material reduction in the lumen of the bowels but tends to perforation into the peritoneal cavity.

The latter causes a very marked reduction in the lumen, and perforation occurs but rarely on account of the predominance of the reparative process.

Our knowledge of appendicitis is almost entirely due to the contributions of American observers and investigators. The first case reported in this country was by Walcott Richards of Cincinnati in 1837. Dr. Edward Hollowell of Philadelphia reported a similar case in 1838. These are two out of a total of four cases reported in the United States for a period of thirty years. During the early part of the fifth decade the vermiform appendix became a subject of frequent discussion. George Lewis of New York in the late fifties published a classical paper which was the first systematic contribution to the literature of the appendix in this country. Forty-seven cases are collected and tabulated.

William Parker of New York reported four cases in 1867, and William T. Bull an analysis of sixty-seven cases in 1873. It remained for Reginald Fitz in his scholarly paper published in 1886 to clear up many obscure questions concerning this subject; to establish the name appendicitis; and to bring about a correct understanding of the morbid conditions affecting this organ, emphasizing their importance.

The surgery of appendicitis is a development of only the last few decades. Parker was one of the earliest surgeons to operate for this condition, one of his cases dating back as far as 1847. The operation consisted in evacuation of the abscess and drainage. He was followed by Weber in 1871 and Bull in 1873. The first successful appendectomy was performed in 1866 by R. J. Hall of New York. Thomas G. Morton of Philadelphia in 1887 performed the first successful removal of the appendix deliberately undertaken for disease of this organ. Sands, McBurney, Edebohls, Deaver, Richardson, and Kelly have in more recent years contributed much to our knowledge of the surgery of the subject.

Van de Warker of Syracuse was the first to call attention in this country to the operative treatment of tuberculous peritonitis. This was in 1887. Three years later Osler contributed a valuable monograph on this subject, in which he reported the result of histological investigation on the process of healing after simple abdominal incision. He concludes: "That tuberculous peritonitis is often a latent affection, localized in the peritoneum, which may even run its course without special symptoms; that as

in other local tuberculous processes, there is in this a natural tendency to healing, which takes place more frequently than has hitherto been supposed; that statistical evidence shows laparotomy to be in many cases a palliative, and, in some instances, a curative measure."

Booker in 1890 was the first to contribute a careful bacteriological study of the summer diarrhea of infants. This suggests the mention of Herter's recent excellent work, published in 1907, on "Bacterial Infection of the Digestive Tract," which comprises a complete review of the subject, together with the results of much original research. The following is an abstract of his findings: The number of bacteria present in the intestinal tract gradually increases as we pass downward from the stomach to the large intestines where there is the most dense accumulation of bacteria and the best conditions for anaërobic growth, while in the jejunum and ileum very few organisms are present. In the stools of healthy nursing infants are found: 1. *Bacillus bifidus communis.* 2. *Bacillus coli communis.* 3. *Bacillus lactis aerogenes.* 4. *Bacillus acidophilus.* 5. *Bacillus aerogenes capsulatus.*

The number of bacteria in the intestines of children fed on cows' milk is greater than in breast-fed children. The difference in number is more marked when the milk has been sterilized since this process destroys a large number of lactic acid bacteria. The varieties of bacteria present in those fed on cow's milk are: 1. *Bacillus coli communis.* 2. *Bacillus acidophilus.* 3. *Bacillus bifidus.* 4. *Streptococus lacticus.*

In childhood and adolescence the *Bacillus bifidus* types are less numerous than in infancy, but the *Bacillus aerogenes capsulatus* and the *Bacillus putrificus* are present, and increase toward adult life when the latter, as well as the coli group, are abundant.

Herter maintains that "The onset of senility may be distinctly accelerated through the development of the intestinal infections in which the putrefactive anaërobes are represented." He divides cases of chronic excessive putrefaction into three types. First, indolic type, characterized by indicanuria due to excessive decomposition of the hydrolyzed proteins producing indol. This type is found in occlusion of the bile duct, and in the chronic intestinal indigestion of children. Second, saccharo-butyric type, due to anaerobic organisms. In a large proportion of cases the *Bacillus aerogenes capsulatus* is the causative agent, at times also the *Bacillus putrificus.* The odor of the movements suggests butyric or caproic acid. On account of the excessive quantity of gas the stools have a low specific gravity and float on water; they contain little or no indol. This condition is frequently found in adults, rarely in children. There is gradual loss of flesh and muscular weakness and frequently signs of premature senility. Third, indolic and saccharo-butyric type combined. In this class are included those cases in which putrefactive anaërobes are abundant with a consequent persistent indicanuria. Nervous symptoms in the form of irritability, mental depression and early mental fatigue are prominent early in the disease. The anemia is a striking feature and may even progress into a pernicious form.

The first case of amebic dysentery recorded in America was reported by Osler in 1890. This was soon followed by the report of cases by Musser, Stengel and Dock; and a most elaborate monograph upon this subject by Councilman and Lafleur in 1891. This latter publication is a most exhaustive treatise upon the characteristics of the amebæ and the pathology of the disease.

Much work upon the nature of bacillary dysentery and the character of the organism producing it has been accomplished by American investigators. Flexner, in 1900, described the lesions associated with this disease and the role played by the Shiga bacillus as the etiological factor. Duval and Bassett, in 1902, first pointed out the association on the *Bacillus dysenteriae* (Shiga) with the summer diarrheas of infants. Howland, in 1904, gave an exhaustive description of the pathology of the Shiga bacillus infection. Flexner and Holt, 1904, reviewed this entire subject, presenting complete bacteriological and clinical studies.

Of greatest importance is the work of Cannon on the physiology of digestion. This investigator has clearly pointed out the salient points regarding the movements of the gastrointestinal canal. He called attention to the fact that the stomach consists of two parts which are distinct from a physiological point of view; the cardiac area, a reservoir for food not affected by peristaltic movements and with no mixing of the gastric juice; and the pyloric area where the food is thoroughly churned and mixed with the gastric secretion. He maintains that the salivary digestion continues for a considerable period in the cardiac area and has shown, moreover, that when carbohydrates are ingested thoroughly, mingled with saliva, 80 per cent more sugar is present at the close of an hour in this part of the stomach than in the pyloric portion, which establishes an important fact regarding salivary digestion. By means of the *x*-ray it was shown that the stomach is not emptied suddenly, upon the completion of the gastric digestion, but gradually and intermittently, the presence of hydrochloric acid producing a relaxation of the pylorus. It was found when carbohydrates, proteins and fats are separately fed in equal amounts they do not leave the stomach at the same rate. Fats remain long, the discharge is slow and continuous. Carbohydrates begin to leave the stomach soon after ingestion (within ten minutes), pass out rapidly, and at the end of two hours reach a maximum amount in the small intestine. Proteins frequently do not begin to leave the stomach during the first half hour or longer, and their departure is slow. These differences are explained by the fact that free hydrochloric acid stimulates the opening of the pylorus, thus allowing the exit of part of the acid gastric contents which is neutralized in the duodenum. This explains why the carbohydrates are quickly thrown into the intestine and why the proteins, which contain hydrochloric acid in combined form and hence less acid in character, are delayed in the stomach to be more thoroughly digested.

The absence of sphincters in the small intestine is compensated for by the presence of what Cannon terms "rhythmic segmentation," *i.e.* separation of the food into a number of segments by contractions of the circular muscle.

Cannon and Murphy studied the movements of the intestine under certain surgical conditions. They found that after end to end suture of the severed intestine "no inefficiency of the gut in the region of the suture was observed; but after lateral anastamosis there was always an accumulation of food in the chamber formed by the apposed loop." They showed also that exposure to the air and unusual cooling do not retard gastric or intestinal peristalsis,

while even the most gentle manipulation of the intestine and stomach greatly disturbs the passage onward of their contents, no food leaving the stomach for at least three hours. There is a remarkable coincidence, as Cannon points out, "in the time which the pylorus holds back the food and that required for the primary healing of intestinal wounds."

In 1902 Cannon established the condition of antiperistalsis as the normal movement of the proximal part of the colon which makes reasonable the presence of a sphincter or valvular structure between the small and large intestine.

In 1908 Cannon first demonstrated the acid closure of the cardia, in which he showed that if the stomach is well filled with a neutral fluid, the fluid is rhythmically regurgitated into the esophagus as a result of the rhythmic relaxation of the contracted cardia. If the fluid is made normally acid, however, the regurgitation ceases, thus proving the acid closure of the cardia.

John S. Boggs, of Indiana, performed the first cholecystotomy in this country in 1867, but it is Marion Sims to whom credit is due for placing this operation, in 1878, on a firm basis in the field of abdominal surgery. A. B. Atherton was the first American to perform a successful operation for perforated gastric ulcer (1894). The operation of appendicostomy was first described by Weir in 1902, who advised its use in treating intractable forms of ulcerative colitis. Finney's pyloroplasty was introduced in 1902, an operation which marked a great advance in gastric surgery. W. J. Mayo, in 1905, described his modified gastrojejunostomy, which formed a great improvement over the older methods of gastroenterostomy. Important advancements in the technique in gastrointestinal surgery were the introduction of the Cushing suture (1889), Halsted suture (1891), Senn's decalcified bone plates (1888), and the Murphy button (1892).

Gastric surgery is greatly indebted to the researches of Cushing and Livingood, who, in 1900, demonstrated the possibility of producing an amicrobic state in the stomach and upper intestines as a preliminary to operative procedures upon these organs.

Time does not permit me to enter into an exhaustive review of other advancements of gastroenterology in America during recent years. I can but refer to a few achievements—the discovery of gastrodiaphany by Einhorn in 1889; the priority in the use of bismuth in the .r-ray examinations of the stomach by Benedict, 1898; the development of radioscopy of the stomach by Einhorn, Williams, Hulst, Cannon, Tousey, Pfahler, Pancoast, and others; the introduction of the bead test by Einhorn; the excellent work of Chevelier Jackson relating to esophagoscopy and gastroscopy; the contribution of Turk on the pathogenesis and pathology of gastric ulcer; and finally to the painstaking work of J. Dutton Steele (our deceased member) on experimental observations upon the effect of intestinal antiseptics.

After the demonstration of the therapuetic value of lavage by means of the stomach tube in cases of dilatation by Kussmaul, in 1867, and the application of this instrument for diagnostic purposes by Leube, in 1871, renewed interest became manifest in the study of gastric disease. This interest was increased by the introduction of the soft rubber tube by Jurgenson in 1870 and its modification by Ewald and Oser in 1875. After the introduction of the test meals of Ewald and Boas, and Riegel in the early eighties, the use of the stomach tube became more and more general, and the value of this apparatus soon became recognized in this country.

Young physicians went abroad to study the new work in the fruitful field of gastroenterology, and from the other side others who had perfected themselves in this line of work turned in this direction to practise their chosen specialty. As the workers increased in number it gradually became apparent that some organization was needed, under whose auspices they could meet and discuss the various problems which were constantly presenting themselves, and by means of which interest could be stimulated in systematic investigation of the digestive processes.

On June 3, 1897, a small band of men met in Philadelphia and perfected plans for the organization of The American Gastroenterological Association. This association has steadily grown and under its auspices much good work has already been accomplished. It has gathered together the physiologist, internist, and surgeon, all interested in this special branch of medicine. The society is still in its infancy, but we have a sufficient number of members residing in various parts of the country that collective investigations can now be undertaken without difficulty. It will be our pleasure to-day to hear of the ultimate results of gastroenterostomy.

At future meetings collective investigations upon the incidence of ulcer and cancer of the stomach may be brought out in a similar manner.

In order to accomplish the best results let us add to our fold all investigators in this country who are accomplishing meritorious work in gastroenterology, so that as the years pass by we may be able to look with pride to this society as the organization under whose auspices the good work in this country has emanated.

In conclusion let us take to heart the words of the renowned author of the "Masterword in Medicine": "You enter a noble heritage, made so by no effort of your own, but by the generations of men who have unselfishly sought to do the best they could for suffering mankind. Much has been done, much remains to do; a way has been opened, and to the possibilities in the scientific development of medicine there seems to be no limit."

A NEW METHOD OF CATHETERIZING THE PYLORUS AND DUODENUM.*

By MAX EINHORN, M.D.,

NEW YORK,

PROFESSOR OF MEDICINE AT THE NEW YORK POST-GRADUATE MEDICAL SCHOOL.

Our knowledge of the functions of the pylorus is quite extensive. Yet our conclusions in reference to its state have been gathered not directly but indirectly from the condition of the stomach and its contents. It is true that this may lead to errors. A direct, so to speak palpatory, examination of the pylorus, would be of considerable value for diagnosis.

If we go a step further, we have before us the duodenum, into which are poured the digestive juices of the pancreas, liver, and duodenum. To be able to examine these accurately would be of undoubted benefit to pathology.

Attempts in this direction have been made long ago, but not with much success. First, I would

*Read before the American Gastroenterological Association at Atlantic City, N. J., on June 11, 1909.

mention Boas's work in this respect. He massages the liver in the fasting condition and then obtains by means of the stomach tube the duodenal contents, which had been regurgitated into the stomach; he then examines it for pancreatic ferments. Frequently, however, on the one hand, the stomach's own secretion is mixed with it; and, on the other hand, the desired regurgitation of the duodenal contents does not always take place.

To get directly into the duodenum by means of

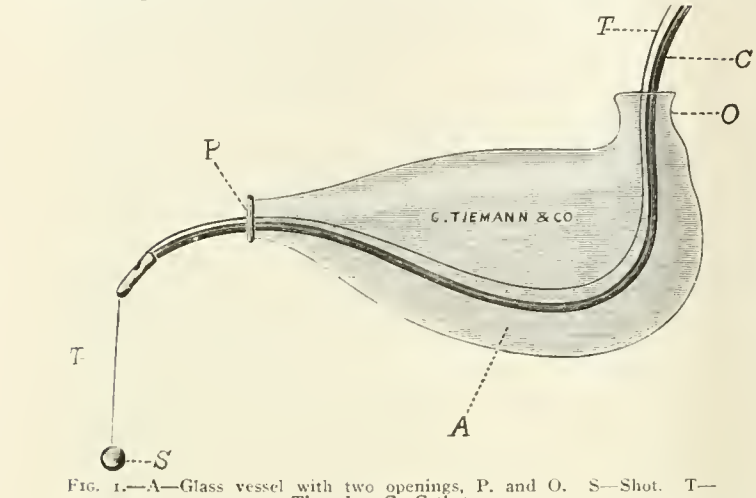

Fig. 1.—A—Glass vessel with two openings, P. and O. S—Shot. T—Thread. C—Catheter.

the tube through the pylorus has been tried by Kuhn with metallic spiral tubes and by Hemmeter* with a balloon which, conforming to the outline of the stomach, is inflated in the stomach and which carries a canal at the lesser curvature, through which a tube should be introduced into the duodenum. The instruments of Kuhn or Hemmeter have not proven practical. In a former paper† I pointed out by means of the duodenal bucket one is enabled to obtain the duodenal contents. This I can confirm by trials on a great many more patients. As a proof that the duodenal bucket is really in the duodenum, the following may serve:

1. The bucket is often withdrawn with bile-stained contents reacting faintly acid or alkaline and showing the presence of bile and the pancreatic ferments.

2. The string is colored golden yellow from 60 to 75 cm. from the teeth, and is white above this. If bile would regurgitate into the stomach and discolor the thread it would be yellow up to 40 cm., *i.e.* the entire part lying in the stomach would be colored. This, however, is usually not the case, and we therefore can assume that the bile was not in the stomach, and that the bucket with 15 cm. of thread was in the duodenum.

3. In withdrawing the bucket we sometimes feel a resistance, caused by the pylorus.

4. An *x*-ray picture shows the bucket in the duodenum (see Figs. 3-7).

Although there is no doubt that with the duodenal bucket we can gather the secretion of the duodenum, yet it appears to be of importance to possess a method, which would enable us to pass a borgie or catheter into this canal, in order to allow this important short stretch of bowel to be examined instrumentally. This can indeed be done by pushing forward a catheter upon the thread holding the duodenal bucket. The catheter is perforated twice at its lower end; the end of the thread is pulled through these holes and the catheter is pushed along the thread into the pharynx, esophagus, stomach, pylorus, and then the duodenum. In using this method we must not proceed too quickly or use force, but must feel our way slowly.

The principle of the method can easily be demonstrated on a vessel with two openings representing the stomach. If you tie a buckshot to a thread and drop it through opening O, and then allow it to emerge at P, by inclining the vessel, holding the thread tight at O, we can pass a whalebone perforated at its lower end over the thread and then shoving it along the thread through O. and P. (Fig. 1) without changing the position of the vessel. If, however, we should try to shove the whalebone, alone, without the guidance of the thread through O, it would touch the bottom of the vessel at once and could never reach P. The conditions in the stomach are similar. O represents the cardiac part of the esophagus, P the pylorus. When the duodenal bucket is in the duodenum we can utilize the thread as a guide and introduce over it a flexible instrument (catheter, bougie, etc.) into the pylorus and duodenum.

According to this principle I have succeeded in several patients to push a catheter through the pylorus and then by means of the syringe to aspirate the duodenal contents (Fig. 2, a). Furthermore, I have passed through the pylorous a catheter the lower part of which carries an inflatable balloon

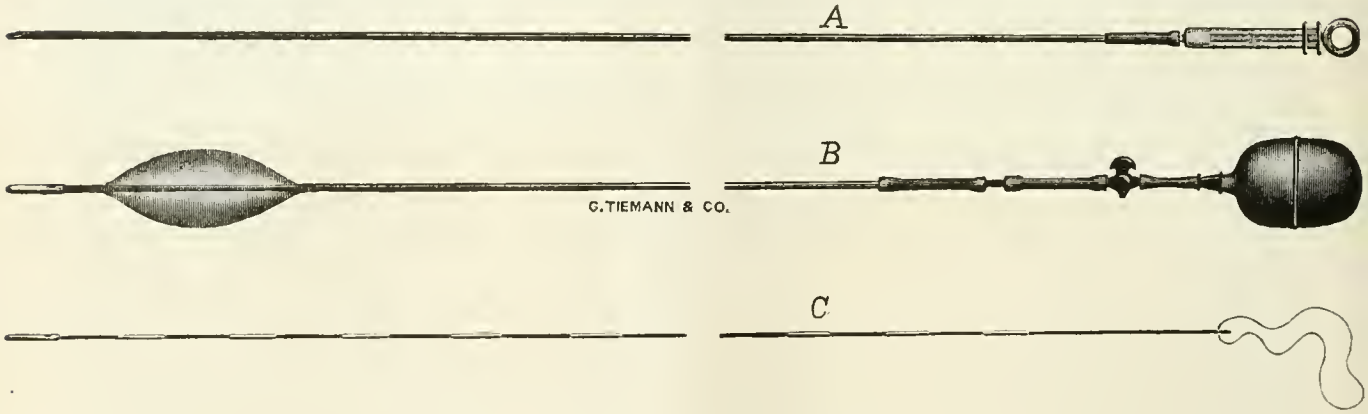

Fig. 2.—Instruments for the exploration of Pylorus and Duodenum. A—Aspirating Catheter. B—Inflatable Catheter. C—Whalebone bougie with metal end and lead paper wrappings.

*J. C. Hemmeter: Diseases of the Stomach. Third edition, 1902, p. 56.

Fig. 3.—*X*-ray photograph of patient, R. S. J., after the duodenal bucket has been in the digestive tract for four hours and the whalebone bougie has just been introduced. The bucket is visible to the right of the spinal column and end of bougie, a little above and to the left of the spinal colmun.

Fig. 5.—Mrs. S. Duodenal bucket four hours in the digestive tract. Bougie with lead paper has been introduced. During its introduction the thread of the bucket was partially withdrawn so that only 63 cm. remained behind. The bougie was introduced to 64 cm. It therefore had to push the bucket before it, when it encountered it; the latter is therefore visible in reverse position beside the bougie to the right of the vertebral column.

Fig. 4.—The same after taking bismuth (one ounce in a glass of milk). The contours of stomach and duodenum are visible; in the latter the bucket can be seen as a dark shadow; to the left the end of the bougie.

Fig. 6.—Mrs. K. Duodenal bucket four hours in; length of the cad. 83 cm. Bougie covered with tintoul. The bucket is visible to the left of the vertebral column. The bougie is visible in its course in the stomach from above to right.

(Fig. 2, b), and after inflation felt on withdrawal plainly the resistance offered by the pylorus. In order to be absolutely sure, however, that the instrument reached the duodenum, I introduced a metal-tipped whalebone bougie, that was covered with tinfoil at frequent intervals (Fig. 2, c), and then had *x*-ray pictures made with and without bismuth.* The pictures demonstrate the position of the duodenal bucket as well as the bougie very plainly (Figs. 3-7, e). Figs. 6 and 7 show especially well the position of the bougie in the stomach and beginning of duodenum. The bucket is already in the small intestine (the length of the thread being 83 cm.). Fig. 7 shows the stomach filled with bismuth. The metal piece of the bougie is visible in the duodenum.† There cannot, therefore, be the

FIG. 7.—Mrs. K. The same after taking one ounce of bismuth in milk. The stomach is plainly visible. The end of the bougie can be recognized to the right beyond the pylorus (duodenum) as an almost horizontal line. To the left of the spinal column below the stomach the bucket can be seen in the duodenum. Whereas in Fig. 6 the long diameter of the bucket is visible, its transverse diameter shows in Fig. 7. The bucket must have turned during the short interval between exposures 6 and 7.

slightest doubt, that we can reach the pylorus and duodenum instrumentally.

This opens new avenues for the recognition and treatment of affections of the pylorus and duodenum.

*All the instruments for the exploration of the pylorus have been made for me by Tiemann & Co., New York.

†The *x*-ray photographs have been taken by Dr. L. G. Cole, to whom I express my indebtedness.

20 EAST SIXTY-THIRD STREET.

Trypsin in Malignant Tumors.—B. Prampolini has treated the following malignant tumors with trypsin without any good results: tumors of the uterus, breast, kidney, inguinal and cervical glands, rectum, etc. The results have been absolutely nil, and the injections have produced much pain and high fever. The author places no faith in the value of this method of treatment.—*La Riforma Medica.*

THE CLINICAL RESULTS OF GASTRO-ENTEROSTOMY;

A PRELIMINARY REPORT.*

BY HENRY WALD BETTMANN,

CINCINNATI,

AND FRANKLIN W. WHITE,

BOSTON.

To determine the result of the treatment of any chronic disease is a difficult matter. A large series of cases must be accurately observed and recorded for a number of years before conclusions can be drawn. The present paper represents an effort to determine by the statistical method the end results in cases of gastroenterostomy. By end results we mean the condition of the patient one year or more after the operation. In order to make our statistics as reliable as possible we have insisted upon certain strict conditions. This has limited the number of cases we are able to present at this time. Only such cases were admitted which had been under the personal observation of one of our own members before and after the operation. Cases were not accepted when the patients were lost sight of shortly after the operation. Some of our members did not have the time or opportunity to respond to our request for case reports, or sent only partial lists of immediately available material. This paper, therefore, must be looked upon as a preliminary report only. We intend to continue our research at least one more year, and hope to present a series at least two or three times as large at a later date. Our study includes the results of gastroenterostomy (in almost all cases posterior) and of Pinney's gastroduodenostomy. We excluded cases of resection, and the older forms of pyloroplasty. We were especially interested in the benign cases, and have separated them from the malignant cases.

After a general survey of results we have classified the benign cases in three main groups. This classification coincides with that into which our clinical cases naturally fall. (1) Cases of pyloric obstruction with active ulceration at the pylorus.

(2) Cases of pyloric obstruction without active ulceration at the pylorus at the time of operation.

(3) Cases of ulcer without pyloric obstruction.

(4) A fourth group includes all cases in which no organic lesion, or at most gastroptosis, was found at the operation. We received, in all, reports of 175 available cases, 150 benign, 25 malignant.

Benign Cases (150).—The immediate mortality (death within 35 days) was 10 per cent. The 15 deaths were ascribed to chloroform, 1; hematoma at the site of operation, 1; shock, 1; paralytic ileus, 1; gangrene of lung, 1; cerebral embolism, 1; pneumonia, 2; peritonitis, 2; subphrenic abscess, 1; persistent vomiting, 3; cardiac dilatation, 1.

Three other patients died of their gastric disorder within the first year following the operation. Seven others were dead at the time of the report, four from causes associated with the gastric trouble, three from causes not so associated. Of 150 benign cases which were operated on, 18 died within the

*Paper presented as part of a symposium at the 12th annual meeting of the American Gastroenterological Society at Atlantic City, June 7, 1909.

first year (12 per cent.); 22 died of their gastric disorder within five years (14.6 per cent.). Six patients are alive, but have been operated upon within one year.

Of the 126 patients who survived the operation, and have been under observation for one year or more, 81 (or nearly two-thirds) were reported as entirely recovered, or well; eight as much better, and thirty-one (nearly 1 in 4) as little or no better. Of the 150 patients, 89, or 60 per cent., were much better or entirely well; fully 30 per cent. died or were little or no better at the time of report.

TABLE I.—BENIGN CASES—RESULTS AFTER ONE YEAR.

	Pyloric Obstruction			Chronic Ulcer	No Lesion
	Ulcer	No Ulcer	Ulcer?		
No Cases	44	37	6	25	14
Immediate mortality	8	1	..	2	2
Well	25	26	4	17	6
Much better	1	2	1	1	..
Little or no better	7	7	1	5	6
Cancer developed	3	1	..	..	..

Table I shows the end results in the various clinical sub-divisions. The immediate mortality is greatest in the class of pyloric obstruction with active ulceration at the pylorus. The end results are approximately the same in cases of ulcer without obstruction, and obstruction with or without ulceration. Fourteen cases were operated on in which no organic lesion, or at most gastroptosis, was found. These patients were mostly neurasthenics with symptoms simulating pyloric obstruction or gastric ulcer. Only six of these patients were benefited by the operation. Two died and six remained unimproved.

Five cases considered benign at the time of operation subsequently developed cancer. In three the operation seemed entirely successful, and the patients were entirely restored to health, but cancer developed seventeen months, four years and five years, respectively, after operation. In the two other cases considered benign by the operator, the development of serious symptoms within six months of the operation suggests the possibility of error.

TABLE II.—SECONDARY OPERATIONS, BENIGN CASES.

15 Patients, 21 Operations.

Cause:		Final Results:	
Vicious circle	9	Well	4
Closure of opening	5	Much better	1
Kink	2	Little or no better	9
Adhesions	1	Recent	1
Dilated stomach	1		
Fistulæ	1		
Vomiting and bleeding	2		
	15		15
Cancer adhesions	1 case	Much better	1

Secondary Operations (See Table II.).—Fifteen patients required secondary operations. Of these six required a third operation, making twenty-one secondary operations. The causes assigned were: Vicious circle, 9; closure of opening, 5; kink, 2; adhesions, 1; dilated stomach, 1; fistulæ, 1; vomiting and bleeding, 2.

Of these fifteen patients, four were eventually cured, and one was reported much better; nine remained practically unimproved. One operation is too recent to determine the result. This table seems to indicate that when secondary operations are necessary, only one patient in three is restored to good health.

It is important to determine if the operations made within the past two or three years have given better results than those made years ago. We have, therefore, prepared a chart (see Table III) tabulating the results according to the year of operation. It would seem from this table that in our series no better results were obtained in the later years than in the earlier.

TABLE III.—COMPARATIVE RESULTS OF RECENT AND EARLIER OPERATIONS.

Operation	No Cases	Well	Much Better	Little or No Better	Dead	
					1 Year	Later
7 years ago	9	5	..	1	..	3
6 " "	9	6	..	2	1	..
5 " "	12	8	..	2	2	..
4 " "	20	11	1	5	2	1
3 " "	12	4	3	2	3	..
2 " "	26	12	3	9	1	1
1 " "	26	18	2	2	3	1
Not dated over 1 yr.	12	8	3	1	..	..

It is of interest to study the effect of the operation upon the gastric secretions. We have notes of twenty cases in which the secretions were studied before and after the operation.

Ten hyperacid cases remained hyperacid. In three, the secretions became or remained normal; in three, the secretions were reduced below the normal or remained so, and in four the free HCl disappeared entirely.

Cancer Cases.—Twenty-five cases are reported. Twenty are in men. Ten patients died within one month of the operation, an immediate mortality of 40 per cent. One is still living two years after operation, another six months, and another four months. Ten patients lived more than four months after operation. Six of these were temporarily much improved, and gains of weight ranging from eighteen to forty-seven pounds are recorded. Two patients received no benefit at all from the operation.

It is curious to note the predominance of the male sex in the cases sent in. Of the benign cases two-thirds are men. Of the cancer cases four-fifths are men. This is probably more than a coincidence. It suggests that the greater prevalence of cancer of the stomach in men is due at least in part to the greater prevalence of intractable gastric disorders in that sex.

GASTRIC SYMPTOMS AND GALL-BLADDER DISEASE.*

By HARRY ADLER, M.D.,

BALTIMORE, MD.

The frequency with which gastric symptoms are encountered in cholelithiasis and gall-bladder disease is so well known; the literature on the subject is so replete, as to offer no excuse for repetition. Disorders of digestion are now looked upon as a part of the symptom-complex of gall-bladder trouble and furnish an aid, rather than a drawback, to diagnosis, when other symptoms referable to this organ are present. There exists, however, a large group of cases in which the symptoms are all referable to the stomach, where examination of that organ demonstrates abnormalities, perhaps, of secretion, of motility, or of position, or any combination of these, where the patient under treatment appropriate to these gastric disturbances obtains a more or less complete relief from his symptoms; and yet, where a sudden attack of severe pain in the liver re-

*Read before the American Gastroenterological Society, June 7, 1909.

gion clears up the nature of the underlying trouble. Two cases in point are as follows:

Case I.—C. S., female; age 43. Mother died of cancer of liver; father had attacks of gallstone colic. Her previous history unimportant. Neurotic temperament. Has been suffering with heartburn, sour eructations, fluid frequently rising in throat. No nausea or vomiting. Appetite good. Bowels constipated. Physical examination: Patient well nourished; florid complexion. Examination of chest and abdomen negative. Urine normal. Free HCl, 62. Total acidity, 84. Motility of stomach, good. No localized tenderness. This case was considered one of hyperchlorhydria of nervous origin; and the symptoms were relieved by the usual treatment of that condition. About two months after treatment was discontinued she was suddenly seized with severe pain in right hypochondrium radiating to the back. This was followed by similar attacks; and an operation showed the presence of numerous gallstones. Since then the patient has had no gastric symptoms.

Case II.—R. M., male; aged 50. Healthy until three years previous, when symptoms referable to the stomach began. Complains of pain in the epigastrium. Appetite good; but afraid to eat on account of pain and distension soon after a meal. Acid eructations and rising of sour fluid into mouth. No nausea or vomiting. Has been taking nothing but milk and zweiback. Has lose 17½ pounds in past year. Physical examination negative. Stomach normal in size and position. Some tenderness in epigastrium. No dorsal tenderness. Free HCl, 42. Total acidity, 76. Patient was treated for chronic ulcer. Symptoms cleared up beautifully and he gained rapidly in weight. Five months thereafter, typical attack of gallstone colic. Operation showed colecystitis with several large gallstones. A rather limited examination of the stomach failed to show evidence of ulcer. Since then he has been well.

Other cases of this kind need not be cited. I have no doubt many of you have had similar experiences. But mistakes of this nature are of importance not only from the standpoint of the welfare of the patient; they reflect discredit on the specialist in diseases of the stomach. They must make us realize that gastrology is but a narrow science; and, unless combined with a broad experience of internal medicine, must inevitably lead its disciples into error and discredit.

While studying the urine in cases of obscure abdominal pain, I was struck by finding traces of bile in several cases where there were no special symptoms indicative of disease of the biliary passages. Rosin's method with tincture of iodine was employed as follows: Tincture of iodine is diluted with alcohol until about the same color as that of the urine to be examined. It is carefully run down on a small amount of the urine so as not to mix but to form a layer. If bile be present at the plane of contact a pale green ring of biliverdin is formed. It is best seen by holding it against a white background. If the amount of bile present be extremely small, the ring appears only after standing a few minutes. This test is by far the most sensitive of simpler methods, giving positive results, when Gmelin's test or its modifications are negative. The following cases will exemplify the importance of carrying out this method:

Case III.—Mrs. S. C., aged 42 years, complaining of "stomach trouble" for several months; oppression and distention after eating; bad taste in mouth; attacks of pain in upper abdomen on both sides; no nausea or vomiting; bowels constipated. Physical examination negative. Stomach and liver normal in size and position. No areas of tenderness. Free HCl, 20. Total acidity, 48. The day following an attack of pain, urine showed a definite ring of biliverdin with Rosin's test. No jaundice. Operation for gallstones showed thickened gall-bladder with several large stones.

Case IV.—Miss G. O., aged 32; slender, neurotic; suffering with lack of appetite, nausea, and occasional vomiting. Has periodic attacks of severe pain in right hypochondrium. No jaundice. Physical examination: Marked gastroptosis and floating right kidney. Paroxysms of pain were attributed to kidney (Dietl's crises). The use of an abdominal bandage was followed by an absence of attacks for about one year when, after a particularly severe attack, the pain being mainly in the left hypochondrium, bile was found in the urine. It had not been looked for previously. No jaundice. On operation a distended gall-bladder containing numerous stones.

The above will suffice for illustration of positive findings, though a number of similar cases might be presented. After a sufficient number have been met with I shall tabulate my findings. Many other cases of abdominal pain could be cited, where the absence of bile in the urine by Rosin's test caused me to throw gallstones out of consideration, and where other findings, as occult blood in the feces, have made the diagnosis of ulcer; or the absence of abnormal signs has consigned the cases to the waste basket of abdominal neuroses; and where appropriate treatment has been attended with happy results. While my experience is as yet too limited to speak with positiveness, or even to tabulate results, it has been, I think, sufficient to demonstrate that by Rosin's test we are able to show choluria in many cases where there is no suspicion of jaundice, and thereby furnish an invaluable aid in this difficult field of internal medicine. The test may also be of value in proving whether a yellow sclera is due to bile or simply to subconjunctival fat. I am in hopes that a more extended experience will prove the importance of this method in cases where attacks of pain are an accompaniment of chronic gastric disturbance. Its simplicity should appeal for its more frequent application. The explanation of the choluria in these cases where there is no occlusion of the common duct lies probably in the extension of the inflammation of the gall-bladder during the attack to the bile passages with interference with the flow of bile, as brought out by Riedel; or on the basis of Minkowski's theory that a disturbance in the function of the liver cells is produced which results in a secretion of the bile in an abnormal direction (icterus per parapedesin).

Bactericidal Power of the Feces of Normal Nursing Infants.—Vitangele Nalli has made an experimental study of the bactericidal qualities of the feces of nursing infants under normal conditions. He finds that the bactericidal powers of the feces are very variable with respect to the different pathogenic organisms. It depends partly on the acid reaction of the medium and partly on the presence of certain special substances. Such substances, in part of microbic origin, belong to the category of thermolabile substances; and a portion of them pass through a porcelain filter. The bactericidal power resolves itself into a process of bacteriolysis.—*Rivista di Clinica Pediatrica.*

CESAREAN SECTION IN PLACENTA PREVIA WITH REPORT OF A CASE.*

By VICTOR E. MARSHALL, B.S., M.D.,

APPLETON, WISCONSIN.

SURGEON ST. ELIZABETH HOSPITAL.

HAVING had during the past year a patient with a central implantation of the placenta with hemorrhage upon whom a cesarean section was performed, it is considered worthy of report. The history of the patient is as follows:

Mrs. J. G. Housewife; age 29. Family history negative. Has had none of the usual diseases of childhood. Had always enjoyed good health until seventeen years of age, when, while walking, she slipped and fell and struck upon her back and developed Pott's disease. A kyphosis appeared a short time later which is still present. At nineteen or twenty years of age she had an abscess of the left middle ear which opened spontaneously and discharged for some time but eventually healed. No deafness followed the abscess. She was married at 23, shortly after marriage became pregnant, and was confined Oct. 7, 1903. As labor was slow and the head failed to engage high axis traction forceps were applied and after some difficulty delivery was effected. The child was dead and all efforts at resuscitation were in vain. It weighed 8 pounds. The perineum was severely lacerated and repaired at once. Convalescence was slow and it was some months before her health was again good. After this she again became pregnant and was delivered Aug. 14, 1905. This labor was again slow for the reason above cited and after waiting some hours for the head to engage, with failure, forceps were applied and extraction of the child proceeded. Some laceration of the soft tissues again followed which was immediately repaired. The child weighed 7½ pounds. As there was some stridor in the child's breathing it was examined and a congenital hypertrophy of the thyroid gland was found to be the cause. It lived 18 hours. The specimen was removed and shown before the Outagamie County Medical Society. Convalescence of the patient was again slow and complicated by much pain about the dorsal vertebræ. Later the third and last pregnancy occurred. Nausea which persisted several months became a distressing feature. Upon Sept. 26, 1908, while in the ninth month of pregnancy, about 1:30 P. M., while standing engaged in some household duties a sudden hemorrhage occurred which was not accompanied by any pain. I saw the patient about half an hour later. Upon examination the os was firm and admitted a finger. A soft bogy mass was felt covering the internal os. The slightest movement in and aside from the examination produced bleeding. Placenta previa was diagnosed. With full knowledge of the previous two difficult labors, of a moderately contracted pelvis, and a rigid and unyielding os, I had great fear for the outcome for both mother and child in case expectant plans were followed. And in face of the fact that a living child was greatly desired I concluded that the interests of the family would be conserved best by resorting to an abdominal cesarean section, and so advised. My associate, Dr. Quick, was telephoned for and arrived within a short time. Dr. Quick concurred in the diagnosis and treatment advised. The vagina was firmly packed with sterile gauze. The husband of the patient consented to the treatment proposed and she was transported to St. Elizabeth Hospital and at once taken to the operating room and prepared for section. After suitable preparation of the abdomen an anesthetic was administered by Dr. Sandborn and a median incision made, the uterus delivered outside the abdomen. The abdominal contents were protected with hot saline compresses. The uterus was incised, a fetal foot seized and the body delivered; the cord was clamped and cut and the child given to Dr. Ritchie to care for. The placenta, which was attached to the lower uterine segment, immediately over the internal os, was separated and removed. The uterus contracted but the contractions were not sufficient to stop the bleeding from the placental site. The lower segment was then packed with plain sterile gauze and the end brought out in the vagina. Some few minutes were consumed in staying hemorrhage. The uterine wall was coapted with two layers of catgut—the first one uniting the muscular layer, the second uniting the serous external layer and infolded to prevent adhesions to parietal peritoneum. The tubes were ligated to prevent future conception. The abdominal wall was closed in our usual way. The operation consumed 37 minutes. The patient's condition continued excellent throughout and her convalescence was uneventful. Both the patient and the baby returned to their home two weeks later. The health of both mother and child has been excellent to date. The patient is a warm advocate of section as a substitute for difficult forceps delivery. She believes she was saved much pain and weeks of invalidism, and the anguish of another still-born child.

It is proposed to discuss cesarean section in placenta previa centralis et lateralis in selected cases with other obstetric measures for the same condition. In the light of the case just cited, and of others occurring in the literature may we not believe that a definite indication can be found which will permit a conscientious profession to substitute the clear cut, scientific cesarean section in some cases of placenta previa for other methods of *accouchement forcé*. The implantation of the placenta over the exit of the fruit sac, either partial or complete is a fell accident of pregnancy fraught with great danger to the lives of mother and child. The danger to the mother is from hemorrhage, from the trauma of a hurried interference to terminate labor, and from infection. The dangers to the child are from asphyxiation, from detachment of the placenta and from the injuries incident to rapid delivery. There is no question that previous results in the treatment of this condition leave much to be desired. And all attempts, and all serious inquiry for the purpose of improving these results must be cordially viewed. There is a notable tendency wherever modern surgery is practised to extend the indications for cesarean section. The absolute indication for abdominal section is, I believe, rapidly covering the ground of what we formerly called the relative indication in contracted pelvis. To drag a child through a pelvis with a conjugate vera of 3½ inches or under is not practicing obstetric surgery according to our light. In the face of the fact that in my case there were a moderately contracted pelvis, two previous difficult high forceps deliveries, and placenta previa, I believe I had ample justification in substituting the abdominal method of delivery. What other methods were available? (1) Packing vagina and waiting for sufficient dilatation

*Read before the Fox River Valley Medical Society, Appleton, Wis., April 20, 1909.

for application of forceps or production of version. (2) Rapid dilatation, manual or instrumental, separation of placenta, and extraction of child by means of forceps, or after podalic version. Williams[1] states that according to Müller, under expectant treatment the maternal mortality varied from 36 to 40 per cent., while for the children it was about 66 per cent., one-half of those which are born alive perishing within the first ten days following delivery. In 178 cases reported by Hoffmeier, Behm, and Lomer, and treated by 11 different obstetricians by combined version by the Braxton Hicks manœuver, the maternal mortality was 4.5 per cent., whereas 93 cases treated by the three operators above mentioned showed a mortality of only 1 per cent. Koblanck reports a death rate of 3.8 per cent. in 467 cases treated in the Frauenklinik in Berlin, and Strassmann, one of 5 per cent. in 100 cases which he delivered personally. According to their figures, the prognosis is from 3 to 8 times more serious in central placenta previa than in the other varieties. The maternal mortality is dependent primarily upon hemorrhage, which is directly due to the condition and which results from deep cervical lacerations, from too rapid dilatation or extraction through an insufficiently dilated cervix and from puerperal sepsis.

The fetal mortality is dependent upon the fact that many of the children are born several months or weeks prematurely or are asphyxiated from placental hemorrhage or die during attempts at extraction through an insufficiently dilated cervix. The fetal mortality has not changed appreciably in recent years. Both maternal and fetal mortality are also dependent upon the variety of the placenta previa, the method of delivery, the condition and surroundings of the patient when first seen.

Can cesarean section in a large series of cases show better results? Of course, no such series can be given as it does not exist. Therefore, if this line is to be followed our indication must be based on a reasonable conjecture or scientific inference. Hence it will be valuable to quote the opinions of some of the leading obstetricians of the world, which I have gathered together.

F. Schauta[2] of Vienna, says: "The introduction of cesarean section as a possible therapeutic measure in the treatment of placenta previa demands careful consideration. I have never performed this operation for placenta previa, and probably shall not do so for some time to come. In the past 10 years my clinic has treated a total of 234 placenta previa, of which 16 were fatal. Equals 6.8 per cent. death rate which is not high. The extreme view of some American authors who pronounce cesarean section to be the only reasonable treatment for placenta previa in general, has been properly repudiated by those who would confine this heroic treatment to cases of placenta previa centralis or lateralis. The results of cesarean section performed in my clinic have certainly been excellent when the patient's genitalia were uninfected. But the prognosis is quite different in cases where the reverse prevailed or the conditions were not favorable. But my belief is that even in cases of placenta previa centralis the commonly practised method is preferable to the cesarean.

C. D. Palmer[3] observes, regarding the cesarean operation for placenta previa; that Dr. Zinke advocates the availability of the cesarean section in cases of central placenta previa with an os closed and rigid and hemorrhage profuse in prima gravidæ. Under the following conditions, undilated os, uncontrolled hemorrhage, child at term and living, normal temperature, and environment favorable, the cesarean section may be seriously considered. He will not insist that it never should be done but think the conditions that indicate it are very rare.

F. A. Higgins,[4] in his Remarks on the Treatment of Placenta Previa, observed: "With respect to the use of the cesarean section in placenta previa I have yet to see a case in which it would be advisable or justified, and such, in my opinion will be rarely seen. The only occasion for cesarean section I would define as: complete placenta previa with both mother and child in good condition before the occurrence of severe hemorrhage, and with the os undilated."

J. B. Deaver[5] reports a case of cesarean section in placenta previa: "Previous deliveries, 4; all by forceps. Child and mother made good recovery. Results of cesarean section for placenta previa are not encouraging. They show an increased mortality for the mother, and the death rate for the child not much decreased. Twenty-five cases have been collected of this treatment. In one case (Storer's) result has not been determined. Of the remaining twenty-four cases nineteen mothers and eight children recovered. Cesarean section is not to be unreservedly commended for placenta previa, and is best confined to cases where cervix is rigid, birth canal contracted and immediate extraction of fetus necessary, and where further hemorrhage would kill either or both."

A. P. Condon[6] of Omaha, reports two cases of placenta previa centralis, upon which he performed cesarean section. There was a good recovery of both mother and child in both cases. He believes the cesarean section to be the proper procedure in cases of central implantation of the placenta where the child is alive and viable. The life of the babe (when viable) is as important as the mother's. It can be done quicker than dilatation, version or extraction. The danger of a ruptured uterus and hemorrhage can be better overcome by section. No obstetrician should attempt a version unless he is equal to a cesarean section.

W. A. Briggs[7] reports four cases of placenta previa in two of which cesarean section was performed. Mother and child both did well in one case, but the child was lost in the second. He believes that serious hemorrhage and infection (consequent in packing and manipulation) could be prevented by early operation, prophylactic cesarean section. In cases of central placenta previa cesarean section of Sanger type should be done at greatest viability of fetus, that is compatible with least danger to the mother. In emergency cases, the Sanger cesarean section with fairly clean uterus should be done (if operator is skilled) and the porro-cesarean of the uterus is deeply infected.

R. Warren[8] of London, reports ninety-four cases of treatment, and says regarding the cesarean section that Tait, Conroy, and Donoghue have each saved a patient by it, but while these results redound to the skill of the surgeons as well as to the stamina of the patients, the mortality, it must be confessed, is very high. Out of ten cases reported, five died. *Accouchement forcé* was not more deadly. In selected cases the death rate of the cesarean section has been reduced to near zero. But a patient with big flooding is not an inviting subject for this operation. Palmer is right who says: "Where the os is undilated (undilatable is better) or hemorrhage uncon-

trollable, the child alive and at term, temperature normal, patient not too weak, then only is the cesarean method advisable."

I. L. Hill[9] read a paper at a meeting of the New York Academy of Medicine (section on Obstetrics and Gynecology) in which he said that placenta previa, among multiparas, was not rare. In one thousand eight hundred cases of which eighty-seven per cent. were multiparæ (four pregnancies usually), the proportion of placenta previa was one to two hundred and twenty-five. The mortality had been understated. There was but little reduction in the fetal death rate of from forty to fifty per cent. He thought cesarean section should be pereformed in the interest of the child, when the case presented long, rigid cervices, complete previa, and a viable child, if surroundings were favorable. Maternal death rate had been reduced, now progress must be directed to getting a decrease in fetal deaths.

Asa B. Davis[10] reports a case of placenta previa, in which the cesarean operation was performed four successive times in four deliveries. The child was saved in each delivery and each time the mother made a prompt recovery. The last delivery was in May, 1905. There was a breach presentation. The abdomen was opened by a median incision, 10 cm. long above the umbilicus. The operation caused the patient less inconvenience than an ordinary delivery.

These opinions are much at variance as one would expect from the nature of the matter in hand. There are many horns to the dilemma, and there seems to be no hope for a future certain indication that will guide for all cases. We may expect to approach a case of placenta previa with not much less fear than in former days. But if cesarean section can be used to extricate us from an occasional heroic situation practitioners should certainly avail themselves of it. I trust I shall not be accused of undue caution when I suggest the following tentative indications for cesarean section in placenta previa: (1) Central or lateral previa (when these can be diagnosed) associated with rigid os—with or without profuse hemorrhage. (2) Child at term and living. (3) Sterile birth canal, *i.e.* norman temperature of mother and favorable surroundings. (4) Justo-minor pelves. Conjugate vera 3½ inches or under. (5) Deformed pelves. (6) History of previous operative deliveries. Finally, to perform cesarean section for placenta previa requires the exercise of individual judgment in any particular case, and no set of rules can be formulated that will help much in the decision, nor do I hope for any fixed indications. Much will depend on the attitude of mind of the operator, his belief in his own aseptic technic. And in addition to these, in private practice at least, he must have the unqualified confidence of his patient.

CHRONIC VARICOSE ULCERS OF THE LEG.

By ALFRED J. BUKA, M.D.,

PITTSBURG, PA.

During five months' association with the inmates of one of the divisions of the Departments of Charity and Correction of the City of New York, personal observation permitted the writer to investigate the cases of a great number of patients who were troubled with "old leg sores." The majority of these cases refused the radical treatment of operation, and for this class a system of medication and treatment was instituted which may prove of interest.

The varicose ulcer is designated by Prof. Da Costa as having for its commonest site the area on the leg above the inner malleolus. Possibly a wider area might be acceptable, confining varicose ulcers of the leg along any portion of the inner side of the leg from below the knee and over the external malleolus. All mention made about chronic varicose ulcers of the leg is derived from the actual handling and treating of about one hundred and twenty cases, presenting a chronicity anywhere from a few months to as far back as fifteen years. The majority of these patients were past middle age and the interesting fact was noted that the varicose ulcer is commoner in the female, and especially common with those who had borne children.

Behind the cause for the varicose ulcer lies the cause of varicose veins. Professor Coplin says "phlebectasia may result from obstruction to the onward flow of the blood," and tumors of the pelvis, pregnancy, etc., are often the underlying cause of varicosities of the leg. Aside from the obstruction theory the disturbances of proper physiological action of the heart and kidneys are factors predisposing to varicosities. Obstruction with pressure of the lesion, be it abnormal growth, pregnancy, or other force exerting intraabdominal pressure, is sufficiently clear as a cause of varicose veins, since overdistention must occur in the veins of the leg when the lumen of the venous radicals of the pelvis is narrowed by pressure. Again, a lesion in the heart causing in any way a weakness in the force of the organ upon the blood stream may be found a truly good cause for overdistention of the veins of the leg because of the heart's failure to pump the blood upstream through the veins of the leg, and resultant stagnation.

The cause of varicose veins can also be attributed to the kidneys, and this can be accepted as plausible since the fact of a deficiency in function or disease in the parenchyma of the kidneys allows an overdistention of the venous radicals, and especially those of the leg, because of gravity holding the body-fluids in this weakened condition of the kidneys, to the lowest level. When the veins of the leg become distended the valves lose their power. Nodules of clotted blood may deposit themselves about these non-functionating valves, and these protrusions and elevations develop to such a degree as to interfere with the free passage of the current. Pressure

from behind may force the blood through a narrow channel and a tortuous route is found by the stream which appears upon the leg as a bundle or string of knots. Since there is always a sluggish flow of the blood in the varicose area, there is a predisposition to effusion of the fluids of the blood into the tissues. This effusion gives rise to the associated edema so commonly seen in the varicose leg. As the protrusions or elevations of the tortuous vein and the edema exert pressure, the overlying structures become thin, the skin shiny, tense, and less resistant. A slight bruise or excoriation, which renders the area susceptible to infection, is the beginning of the ulcer, and with the irritation caused by the viscid excretion from the site of the infected area an eczema is excited about the ulcer. This eczema causes intense itching, which the patient attempts to relieve by scratching. Through such irritation further abrasions, about the non-resistant area of the ulcer, are caused and as a result the ulcer grows rapidly larger. Very often the patient gives only a history of trauma as the beginning of the ulcer and never in such instances does he attribute the development of the ulcer to his "swelled veins." In the leg the long saphenous vein, which has no great muscular covering over it, is the commonest vein giving rise to varicosities. As a varicose vein becomes distended the pressure upon the overlying tissues will cause an atrophy of these structures, and in the event of injury to such tissues there is little or no resistance. Inadequate blood supply or sluggish circulation in a varicose area predisposes to ulcer formation, because there is not sufficient aid in such an area to combat an infection which may develop during an abrasion or excoriation from a trivial bump.

Usually the patient complains of a weakness of the affected leg. Commonly he mentions the fact of his having swelled veins for years which never gave him trouble until the day he fell or bumped his leg, but it is surprising that he complained little of pain or tenderness over the site of the ulcer, although it may have been very large. Edema about the site of the lesion, the associated weakness of the extremity, and the failure to close the "running sore" are the factors which usually bring the case to the physician. Frequently, after the ulcer has been of long standing, there develops an intense itching and redness about which the patient will complain. Hence the commoner subjective symptoms are: (1) weakness of the affected leg; (2) a history of swelled veins; (3) edema; (4) intense itching.

Usually, when the patient came to the doctor for the first time, he exposed his limb bandaged with some old cloth or rag that was used repeatedly for the dressing. This dressing, as a rule, was a heavy muslin bandage covering the foot and leg well above the area of involvement. The physician was never surprised to learn, upon questioning the patient, that the leg had not been dressed for anywhere from five to ten days. Ordinarily the bandage over the site of the ulcer was wet through with a brown or grayish discharge which emitted a most disagreeable, musty odor. Upon exposing the ulcer, the odor was that of decaying meat, and the area presented a liver-colored patch of granulations, covered over with a thick, grayish white mucopurulent exudate. There was surrounding the ulcer, usually, an undefined skin area of redness for which the patient would reach with his finger nails as soon as the bandage was removed. An intense itching seems to start in the affected part when it is exposed to the air. The inflamed skin area, upon closer examination, was seen to be undefined, running very gradually into the area of healthy skin. The skin area was scaly, dry, and peeling. The skin underlying the scales was tense and glistening and the entire condition was identical with eczema. It seems entirely due to the irritating viscid and glairy exudate from the ulcer. The edges of the ulcer were thick and sloped gradually to its floor. The leg about the margin of the ulcer was especially red, often edematous, and pitted on pressure. Not uncommonly the floor of the ulcer presented granulations above the level of the skin, and these were of the exuberant type, large, rather dark, and bleeding after being touched. The ulcer increased in size by its destruction of the surrounding atrophied tissues, which had become further nonresistant to the irritating exudate from the ulcer because of their eczematous condition.

As to the methods given trial along the lines of minor surgery the following were used: (1) skin grafts; (2) epidermis grafts by means of blistering agents; (3) destruction of exuberant granulations; (4) scarification of ulcer bed; (5) scarifications of ulcer margins; (6) combined methods.

Skin grafts were never successful at a single sitting and in several instances the grafts became a part of the old ulcer again. By means of cantharidal plaster (in one piece) blisters of the epidermis were made which after twenty-four hours were punctured. The loose epiderm was cut off under sterile and antiseptic precautions and permitted to rest over the blistered area until the ulcer was carefully cleansed and rubbed with gauze thoroughly wet with warm normal salt solution. The ulcer which had previously been treated so that healthy granulations had formed bled freely after the rubbing and the margins of the ulcer were scarified. With dry, sterile gauze the ulcer bed was dried; then by means of two pairs of tissue forceps the skin was carried from the site of the blister to the ulcer. The graft should be large enough to readily cover the ulcer. Either the opposite leg or high up on the same leg was always used for blistering. The treatment for the blister was the same as that for a burn: 1 per cent picric acid solution for first dressing, after which dressings of zinc oxide ointment were used until healed. Destruction of exuberant granulations was done with the curette, carbolic acid, and alcohol, or lunar caustic. Where any of these procedures were painful to the patient a 2 per cent. cocaine injection was used. Scarification of the ulcer bed was used where granulations were tardy. Scarification of the ulcer margin was used in almost every case to stimulate granulations and to cause a pulling together of the edges. The combined method was two or more of the above procedures upon any one ulcerous site, and no case calling for the knife in the realm of minor surgery was treated without this method.

In treating any lesion the primary procedure is toward relief of the aggravating symptoms. After this, efforts at repair and removal of the cause of the lesion are made, and finally the resultant complications diminished. It is just in this way that the treatment of the varicose ulcers of the leg was instituted in the cases handled; the weakness, edema, itching, and other symptoms were overcome; efforts at prevention of congestion and stasis in the venous radicals of the extremity were endeavored; and the ulcer itself was treated with efforts at prevention from further infection by proper sterile and anti-

septic precautions being exercised in the treatment of the site. The practitioner has, in the past, been more or less indifferent to Nature's provisions for repair and care of diseased parts, and medication has been, in many cases, lauded when Nature's repair was the real factor in restoration to health.

In the treatment of the cases there were two great divisions made of the number, regardless of the chronicity or extent of the area involved, viz., walking cases and resting cases. The walking cases constituted that list of patients who could attend the regular tri-weekly clinics, while the resting cases belonged to the list of patients who remained in the hospital wards. With both classes the same line of treatment was instituted, and in conjunction with medication, Nature's remedies, viz., rest, elevation, and aeration, were applied whenever it was possible.

Upon the occasion of the patient's first visit the ulcer was curetted so that all exuberant granulations were removed from the ulcer floor. The ulcer was mopped with sterile cotton, saturated with a 1 per cent. or 2 per cent. solution of cocaine or beta-eucaine, to render the treatment as painless as possible. Certain cases in which the margins were deep were treated after the curetting of the bed by lifting the margin and scarification of the ulcer bed. If the margin and bed bled freely the hemorrhage was allowed to go on for a few minutes. If the ulcer bed showed a tendency to tardy or poor granulations it was livened up by painting with iodine or by destruction of the granulations with lunar caustic, 50 per cent. silver nitrate, or pure carbolic acid to be washed off with alcohol. After the treatment for exuberant or tardy granulations, the ulcer area was treated with warm 1-2000 or 1-5000 bichloride dressings. Sterile gauze pads (about 4-6 inches) were placed in the warm bichloride solution, and after a free removal of the excess solution, they were placed upon the ulcer. Rubber tissue was placed over the gauze and the part was bandaged with 3-inch gauze (not too tight.) If the patient remained in the wards rubber tissue was not used and the bandage over the ulcerous area was kept wet with the bichloride solution. All patients were instructed about the importance of rest, elevation, and aeration. After forty-eight or seventy-two hours the patients presented themselves for examination either at the clinics or in the wards. Each patient had the same kind of dressing placed upon the ulcer again and internal medication was instituted. Fluid extract of ergot was administered 7 to 15 minims three times a day, and this remedy was to be continued indefinitely. (It is to be remembered that all cases received direct attention every forty-eight or seventy-two hours, and when an application is spoken of as having been used for one or two or three dressings the writer wishes the time interval between dressings to be considered.)

Usually at the third or fourth dressing the ulcer appeared as a bright red, freely bleeding area and upon closer examination small pinhead granulations could be seen. At such a time treatment for the edema was instituted along the line of any of the saline purges in the morning (a wineglassful of a saturated aqueous solution) and the infusion of digitalis one to two fluid ounces three times daily, until the edema lessened. Edema appeared rarely in the lean or wiry type and the fat and boggy patient could only profit from the purges and the infusion of digitalis. In all cases the free daily elimination of the excretions was desired. The cases were all instructed not to allow the bowels to remain blocked for longer than twenty-four hours. The musty or foul odor which came from the loosening of the early dressings disappeared about this time. The previous dressings of bichloride were applied for the purpose of antisepticizing the affected area, but for the next dressing remedial measures were called into use.

For the stimulation of healthy tissue granulations iodoform, aristol, or bismuth subgallate were used; dusted directly over the ulcerous area. Acetanilide and phenacetine were also frequently combined with any of the dusting powders mentioned. Where there was an eczematous involvement about the ulcer the free dusting of any of the powders and salicylic acid, as a powder, seemed to bring on the best results. Wherever it was possible to keep the area involved moistened with bichloride 1:5000, it was done. There were several advantages in keeping the affected area wet with this solution; it diminished the chances of further infection; it softened the tissues, thus rendering them more susceptible to medication, and it prevented the applications from sticking to the healing ulcer. Whenever a complicating eczema spread itself over an extensive area, zinc oxide was freely applied upon the outer limits of the irritation, and besides this an application of tincture of iodine was applied to what appeared to be about the outer zone of eczema. Such applications were often repeated for several sittings and were, as a rule, kept up until the patient complained no longer of itching at the margins of the ulcer. The liberal use of salicylic acid powder over this area, and often a combination of this powder with any of the ordinary surgical dressing powders, produced a lessening of the itching. The combination of salicylic acid and iodoform, aristol, bismuth, or bismuth subgallate produced most gratifying results. There were many complaints about the burning pain from the use of a combination during the first few dressings, but the powerful stimulating and absorbing powers of the drugs were too encouraging to be abandoned. Usually after the third application patients bore the powders very well. The belief in the use of powders arose from the observation made, viz., they bring the exudate more rapidly to the surface and tend to centralize it. Powders were usually applied at anywhere from three to nine dressings, after which there was a sufficient formation of new granulation and all irritation from the eczematous area had ceased. At about this time—this being sometime between the fourth and sixth week—an opalescent film had developed upon the ulcer surface. It is at this stage that the salves and unguents may be applied; *i.e.* after the granulations are covered with a protective layer. Many cases requested the changing of the powders to salves before this stage had been reached, because of a continued pain from the stimulating powders, but in no instance where this was done were the results gratifying. As is well known, almost all unguents form a nidus for the propagation of bacteria, and since this is the case we should not expose an open ulcer to infection after it has been rendered sterile. A good stimulating and healing unguent is a 10 per cent. or 20 per cent. ichthyol ointment. Either strength is good alone where eczema is not a complication of the ulcer, but when it coexists either of the strengths may be used with salicylic acid and zinc oxide. All dressings with unguents should be thickly lathered.

For the rapid healing of any affected area, presenting an open or abraded surface, there seems nothing so beneficial as rest. If an ulcer is bound

up or bandaged, as in the instance of walking cases, it stands to reason that little cure or repair can be expected as a result from the applications, as long as there is motion with resultant irritation from the bandages. From the use of the part the applications of the remedies are often spread beyond the site where they are intended to do their work. The using of the affected part calls for an increased blood supply, and this is just what should be guarded against, because a congestion already exists. This occurs from the condition of the venous radicals. The veins are incapacitated and damaged, they cannot functionate properly, the blood does not return unobstructedly from the extremity, it lies in the venous channels until the liquor sanguinis, as an exudate into the tissues, produces the edema so common with varicose ulcers. It seems reasonable, at least, then, to say that rest increases the chances for repair by lessening the irritation to the ulcerous site and by decreasing the tendencies for edema to the part.

Elevation was used with the idea in view that the arterial tension in the part would be lowered while the venous return would be favored by gravity; thus a great tendency to congestion would be overcome. In all instances where the patient was a walking case he was instructed to sit down as much as possible for rest while he elevated the affected extremity on a chair or table to the level of his buttocks, and preferably six or eight inches above the level. In the resting cases the extremity was always elevated upon pillows and kept six or eight inches above the level of the mattress for days at a time. When the bed clothes were changed the leg was lowered to the mattress level for a change for the patient.

Aeration as a most curative measure could be used only in a limited number of cases. In these instances, however, the results were most gratifying, but the patient needed great attention. The ulcerous area was exposed to the air and treated as follows: All medication was dusted upon the part where indicated and over the powder a light layer of gauze was spread to keep the part free from flying particles and insects. When wet dressings were required there was only a light layer of gauze upon which the wet applications were dropped.

I wish to emphasize my convictions in regard to treatment. There seems to be a fallacious notion about the handling of ulcers from the standpoint of medication; the changing from one application to another is very important and the physician should know when to do this. Certain drugs, after bringing about a condition of improvement, will undo their good work during continued application. One should know when to use drugs and know also when to stop them. When it is possible we should allow Nature's remedies, rest, elevation, and aeriation, to perform their cures and never fail to impress the patient with the importance of these.

As a strict requirement in the treatment of varicose ulcers, the patients are instructed not to keep the knees flexed while sitting or lying down, as this flexion retards the return flow of blood in the venous circulation.

Two Cases of Poisoning of Infants from Anise Water.—Giovanni Berti describes two cases in infants in which severe symptoms of poisoning occurred after the use of anise water. The symptoms were those of excitation, followed by stupor and etheral narcosis of rapid invasion, short duration, and rapid disappearance, and ending in intestinal catarrh.—*Rivista di Clinica Pediatrica.*

A CASE OF TRICHINOSIS.*

By LINDLEY DOBSON, M.D.

ASHLAND, MAINE.

The patient, Mr. Andrews, aged 27, was seen by me January 24, 1908. His family history is unimportant. Nothing in the personal history of any moment, excepting an attack of the small pox in 1903, and one of typhoid fever in 1905, from both of which he fully recovered. His present illness commenced about January 20, 1908, with aching of muscles and general malaise. There were no gastro-intestinal symptoms.

On January 24, there was some fever and accelerated pulse. Limited to the upper part of the face, including the upper lip, there was some edema lasting several days. The urine was scanty, not over eight ounces in twenty-four hours; no albumen, no sugar, reaction acid, specific gravity 1,022. On January 26, symptoms remained about the same, with herpes labialis on the right side, added. On January 27, temperature was 100.4°, pulse 86, respiration 20. He complained of muscle pains. The heart sounds were distant and feeble. Some moist râles were present throughout both lungs.

On January 30, on sitting up in bed, he had a severe attack of syncope. From the step ladder rise of temperature from the first of the attack, I thought Mr. Andrews might be developing typhoid. The Widal test made proved negative. A differential blood count gave: polynuclears, 56 per cent.; eosinophiles, 31 per cent.; lymphocytes, 11 per cent.; transitionals, 2 per cent. This eosinophilia taken with the local facial edema and muscle aches cleared up the diagnosis. Patient was given five grains of santonin.

On January 31, the patient complained of pain on protruding the tongue, and there were local tender points in the calf and pectoral muscles, especially near their tendinous parts. On February 1, the patient was given five grains of santonin. Examination of the stool for *Trichinellæ* proved negative. On February 2, the patient was given calomel, three grains. He was also given glycerine, one-half ounce every hour for several doses. On February 3, a saline cathartic was given in the morning. In the afternoon the patient had three large liquid stools, which, after some searching, showed many *Trichinellæ spirales.*

On February 6 the blood examination showed: red cells, 3,900,000; hemoglobin, 67 per cent.; white cells, 10,000, of which there were polynuclears, 55 per cent.; eosinophiles, 16 per cent.; lymphocytes, large and small, 24 per cent.; large mononuclears, 2 per cent.; transitionals, 3 per cent. One baso-myelocyte in 500 cells counted. On February 11, the temperature and pulse were normal and the patient's recovery was uninterrupted from this period.

On April 22 differential blood count showed; polynuclears, 67 per cent.; small lymphocytes, 14 per cent.; large lymphocytes, 6 per cent.; eosinophiles, 8 per cent.; large mononuclears, 3 per cent.; transitionals, 2 per cent. One mast cell in 300 counted.

Extreme weakness, profuse sweating, and sleeplessness characterized the whole sickness, and after recovery there was considerable falling of hair. The eosinophilia lasted at least three months.

Before 1908 I had never seen a case of trichinosis;

*Read at the meeting of the Maine Medical Association, June 16, 1909.

and, while some of the classic symptoms were well known to me, it was only through knowledge of Dr. Brown's study of the blood in this condition at Johns Hopkins, that I was led to diagnose the case. In my tardy diagnosis of the case, which I believe proved almost fatal to the patient, I ask your most lenient criticisms.

Infection with the *Trichinellæ spiralis* occurs so seldom in this country that the above report may be of interest to you. It is possible, however, that trichinosis is not so rare as supposed. Dr. H. U. Williams in the *Journal of Medical Research* for July, 1901, states that in 505 cadavers taken at random the *Trichinella spiralis* was present in 5.34 per cent. Dr. Baben in the *Annals of Surgery*, March, 1908, reported the third case of this parasite found in carcinomata in patients with no history whatever of trichinosis. From these facts I am led to believe that some cases of mild infection have passed unrecognized.

While it is not the purpose of this paper to deal with the diagnosis of this disease, I wish to refer to a recent paper by Drs. Herrick and Janeway wherein they state the finding of the embryos in the blood. The blood is laked with 3 per cent. acetic acid solution and the sediment obtained with the centrifuge is examined for the embryos. This method will prove more certain in its results than will an examination of the stools, and it will be much less painful and repellent to the patient than the examination of a portion of excised muscle.

PERMANENT BLOOD-PRESSURE RECORDS.

By BRYCE W. FONTAINE, M.D.,

MEMPHIS, TENNESSEE.

The importance of sphygmomanometry has necessitated the adoption of a great many instruments, of which those with a mercury manometer, wide armlet, and with devices for recording the systolic and diastolic pressures graphically, are the most accurate.

In instruments of this type, in order to determine the pressures, it is necessary to watch both the manometer and the writing lever at the same time; and, when the estimate has been made, it is entirely a matter of one's memory as to just what was the proper reading.

By altering the arrangement of the tambours on the Hirschfelder-Erlanger instrument, I believe I have simplified the matter (Fig. 1). With this arrangement it is only necessary to watch the manometer, and after the estimate has been made there is a permanent record of both pressures, systolic and diastolic, which, like the sphygmographic tracing, can be attached to the history sheet.

The writing lever attached to the small tambour is made the same length as the lever on the larger tambour of the sphygmomanometer and is adjusted beneath it; leading from this smaller tambour there is a rubber tube (Fig. 1, *a*).

An idea of the blood pressure of the individual to be examined is forecasted from the age and the disease from which he suffers, and the kymographion is made to revolve and the levers adjusted accordingly.

When the manometer registers slightly above that figure, at that moment pressure is made upon the smaller bulb, which produces a marking with the smaller lever upon the kymographion, and at each successive fall of ten millimeters in the column of mercury in the manometer pressure upon the bulb is repeated.

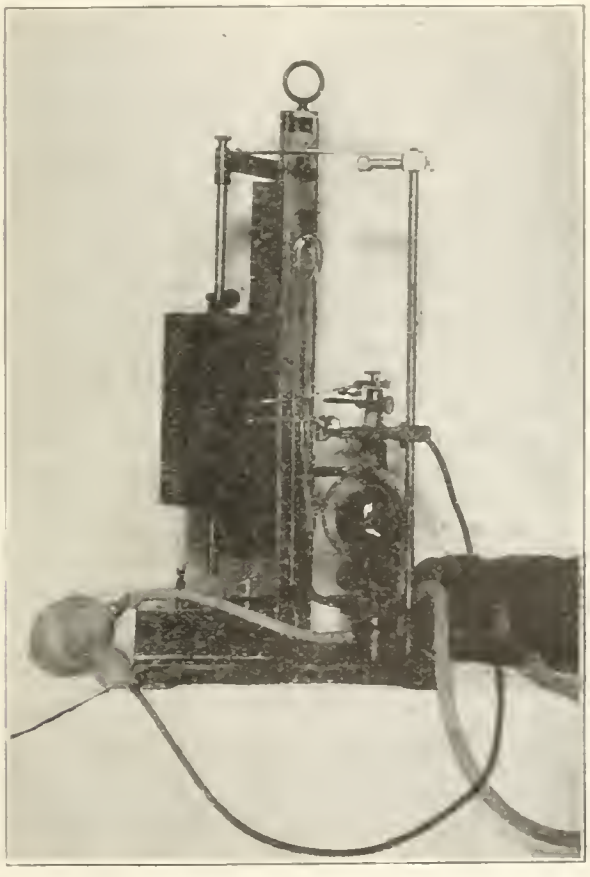

Fig. 1.—Author's modification of the Hirschfelder-Erlanger sphygmomanometer.

The record will then show interruptions in the lower line, at every ten millimeters in the fall of the blood pressure, and knowing the beginning of the record to be, for example, 160 millimeters, the record of the manometer corresponding to the first abrupt increase in the amplitude equalling the systolic pressure, and the last maximal amplitude equaling the diastolic pressure, can be accurately recorded and kept as a permanent record by coating the smoked paper with shellac.

AN ENEMY TO THE SOUTH.

ONE of the most conspicuous of the minor triumphs of medicine in recent years—it would be more just to say one of the greater triumphs—is the discovery of the cause of the anemia which is so marked a feature among the poorer whites in the South outside the larger cities. The anemia was long since recognized, but its cause was not known, and when one gave it a thought it was usually attributed to poor food, the males of the family being shiftless and too lazy to earn their bread. Stiles discovered, however, that the anemia was due to the presence of uncinaria, or the hookworm, in the intestine, and that the laziness and general good-for-nothingness of the poor whites were not moral defects, but were due to actual physical inability to do hard labor as well as to a mental disinclination, both being the direct result of this same hookworm-induced anemia. The whites are not the only sufferers, however, for the negro as well harbors the parasite, but they are the greatest sufferers, negroes seeming to have acquired a partial immunity to the poison of the hookworm. The latter are, as Charles Wardell Stiles points out in one of his recent writings on this subject,[1] carriers of the hookworm, suffering comparatively little themselves, but serving as breeders of the worm and sowers of its seeds, to the lasting injury of their white neighbors. It is quite likely also that the South owes the introduction of the disease to the negro who brought the parasite from Africa and polluted with its eggs the soil from the Potomac and the Ohio to the Gulf.

Although the negro does not suffer directly from uncinaria infection in nearly the same degree as does the white, the indirect effect, Stiles thinks, may be in him most deplorable. The injury to the intestinal walls may not improbably interfere more or less with digestion, while the poison excreted by the parasite must affect the red blood corpuscles to a harmful extent even if it does not induce the high degree of anemia that it does in the white man. It therefore reduces the resisting power to infections and especially, Stiles contends, to pulmonary tuberculosis. He ascribes the terrible fatality of this disease among the negroes of the South largely to the almost universal presence of uncinariasis. He recalls the observations made recently in Manila regarding the indirect effects of hookwork infection. When the Americans took charge of Bilibid prison the death rate was 238 per 1,000 per year; by improving the sanitary conditions this death rate was reduced to about 75 per 1,000; here it remained stationary until it was discovered that a very high percentage of the prisoners were infected with hookworms and other intestinal parasites; then a systematic campaign was inaugurated to expel these worms, and when this was done the death rate fell to 13.5 per 1,000. The whites suffer more severely from the direct effects of the poison, many deaths among them being attributable to this cause, but undoubtedly they also suffer from the indirect effects, and their death rate from all diseases would be reduced in equal measure were the hookworm exterminated.

The South suffers in other ways than pathologically from the prevalence of this parasite, and its economic advance beyond a certain point will be impossible so long as the ravages of this worm are allowed to go on unchecked. The shiftlessness of the poor white and the negro is not the effect of climate or of class, it is the result simply of the hookworm infection—an infection made possible, even inevitable, by the filthy habits of the southern peasant—both white and black. The disease also puts a mental handicap upon the children. Stiles says: "As nearly as can be estimated (admittedly a rough estimate) the physical condition of the southern country school children with whom I come in contact is such that they cannot possibly assimilate much over 70 per cent. of the education they receive; in other words, somewhere about 30 per cent. of the educational efforts are wasted, and prominent southern educators have stated that this estimate is very conservative."

As is known, the hookworm does not multiply in the intestine of its host; it deposits its eggs there and these are then discharged in the stools and hatch out in warm, damp, dark places. The young worm enters the body of a new host, possibly in the water or on salads or vegetables eaten raw, but its chief mode of entrance is probably through the skin of the feet and ankles. The wearing of shoes will therefore prevent infection in a measure, but the attempt to shoe the children of the southern small farmers and all the pickaninnies as well, would be a task from which even the most daring sanitary reformer would shrink. The only effectual mode of attack of the hookworm is to destroy the stools containing its eggs, but this, too, seems a hopeless undertaking when one thinks that only about 31 per cent. of the farms in some States of the South have privies of even the most primitive and insanitary sort, the natives in most cases defacating wherever they happen to be when the desire moves them; many of the country schoolhouses and churches also are unprovided with this convenience.

Theoretically the eradication of hookworm disease could be accomplished in a short time by treating all the harborers of the parasite with thymol, shoeing the entire population for a time, until the

[1] "Public Health Reports" of the Public Health and Marine-Hospital Service, July 30, August 20, October 1, 1909.

present soil pollution could be remedied, and burning or chemically treating the stools of the infected. That such measures as these could never be universally or simultaneously carried out is evident, but much can be done by individual and concerted effort. The charitably disposed and the patriotic people of the South could do no greater good to their land and its inhabitants than by organizing leagues for combating the hookworm, after the plan of the antituberculosis leagues, for it is no exaggeration to say that the regeneration and the lasting prosperity of the South depend absolutely upon the extermination of this detestable parasite that is literally sucking its life blood.

AGGLUTININS AND BACTERIOLYSINS IN CHOLERA.

The diagnosis of Asiatic cholera in the acute stages of the disease offers but few difficulties to the modern physician, trained in simple bacteriological technique. With the use of the common nutritive media and a thermostat the causative agents of the diesase may be demonstrated in the dejections of the patient within twenty-four hours. On the other hand, the diagnosis of sporadic cases or such as are suspected to be cholera only after the first week or more of the disease has passed, cases, that is, that are most likely to be met with in the United States among immigrants and sailors, is quite difficult. In these patients, the microorganisms are usually no longer demonstrable in the feces, and clinically the picture of the disease is often very similar to certain advanced stages of typhoid fever. Dr. Swenson of Kieff has recently attempted a study of the newer biological diagnostic methods in connection with the recent cholera epidemic in Russia and reports his findings in *Russkii Vrach*, No. 30, 1909.

He first examined thirty-seven patients in various stages of cholera for the presence of specific agglutinins; the nature of the disease was conclusively proved in all but one of these patients by the cultivation of the cholera vibrio from the feces. However, only thirteen of them gave a positive reaction, their sera agglutinating the vibrios in dilutions from 1:30 to 1:50. Moreover, the same agglutinating property was found in several persons who had never suffered from the disease. Agglutination, therefore, could not be safely used in the diagnosis of sporadic cases of cholera. Swenson then studied the serum of the patients with reference to its bacteriolytic power, using the old test of Pfeiffer, which consists in injecting definite amounts of serum and of a pure culture of the cholera vibrio into the abdominal cavity of guinea pigs. The presence of bacteriolysins was shown by the loss of motility and the transformation of the vibrios into spheroidal degenerative forms; at the same time the amount of serum required to produce this phenomenon served as a measure of the activity of the serum in this direction. This time bactericidal bodies were demonstrated in the sera of almost all patients suffering from cholera as well as in many patients who had recovered from the disease. However, the test could be used as a diagnostic evidence only when quantities of serum smaller than 0.5 c.c. were sufficient to exercise a bacteriolytic effect, for normal sera often produced a similar effect when used in large amounts. Neither agglutinins nor bacteriolysins seemed to play any decisive rôle in the mechanism of immunity, for their presence and amount had no relation to the severity or stage of the disease.

Swenson does not, of course, attribute any but corroborative or partial value to the phenomena of agglutination or bacteriolysis in the diagnosis of cholera. Yet, though not pathognomonic signs they may prove of great importance in the diagnosis of sporadic cases or those of patients who travel from centers of infection before their disease has become manifest.

TROPICAL DYSENTERY.

At the recent International Medical Congress at Budapest, Dr. Galli-Valerio read a paper on the etiology and prophylaxis of bacillary dysentery. He laid especial stress on the fact that the disease is caused not by one bacillus but by many bacilli belonging to the Shiga group of these organisms. According to the author the disease in all its varieties is spread chiefly by personal contagion either from sick persons or from healthy "carriers" of the bacilli, and either directly or through fomites; by water, which plays a most important rôle in the spread of the disease; by means of flies, as proved by experiments; by milk, which may be infected by flies or by the addition of infected water, or by the washing of vessels with such water; by vegetables, and by the soil and dust. The main prophylactic measures recommended were placed under the following headings: 1. As rapid diagnosis of the first cases as possible; 2. Compulsory notification of all cases; 3. Strict isolation of the sick, and 4. Disinfection of the excreta, linen, etc., and of the room occupied by the sick.

At the recent meeting of the British Medical Association Cantlie dealt with the treatment of what he termed chronic recurrent dysentery. He is of the opinion that drugs have little effect upon the condition and that diet should aim at the administration of food causing but a minimum of excretion. All farinaceous foods should be excluded from the diet and milk completely withheld. Pounded meat, eggs, jellies, etc., should constitute the means of sustenance when an attempt is made to control local congestion in the sigmoid. Enemata are useful, and warm sea-water is the best fluid for this purpose. The most valuable portion of Cantlie's paper was that which dealt with operations upon the colon for dysenteric lesions. The author expressed himself as strongly in favor of operative measures in perhaps the majority of cases. He is of the opinion that when the disease is quite chronic, and should the dysenteric attacks occur again and again, opening the sigmoid flexure will be found to be theoretically and practically an efficient means of treatment, because the disease in 90 per cent. of such cases is at the junction of the sigmoid flexure and rectum, and an opening at the upper end of the sigmoid will be found to be well above the lesion. Through the opening in the sigmoid bougies may be passed downward through the stenosed portion, thereby

curing the cause of the lesion. Cantlie also holds the view that removal of the entire colon is a justifiable operation when the walls of the whole length of this portion of the bowel are hopelessly destroyed. He does not regard ipecac as useful in warding off liver abscess, nor does he consider that hepatic abscess is necessarily or usually preceded by general hepatitis. Many of those who took part in the discussion upon Cantlie's paper took the view that operative measures were not nearly so frequently needed. Chronic dysentery in an advanced condition is, however, in most instances practically hopeless of cure, and in such cases an operation may do good.

A resolution which was brought forward at the International Congress at Budapest and unanimously adopted was to the effect that dysentery in any of its forms should be added to the list of compulsorily notifiable diseases in all countries, as it is at present in some, since it constitutes one of the grave epidemics that may appear in any country.

Camphor in Pneumonia.

The idea that pneumonia is a self-limited disease and not amenable to treatment is widely held by many excellent practitioners who regard with great scepticism the testimony offered from time to time concerning the value of certain remedies which are suggested as of service in cutting short or aborting the course of the disease. The latest offering to the list of drugs recommended in the treatment of pneumonia is made by Seibert, who, in the *Münchener medizinische Wochenschrift* for September 7, 1909, reports his results in treating a number of cases of pneumonia with hypodermic injections of camphor. The author believes that the action of the camphor is twofold—stimulating and bactericidal. Until two years ago Seibert had used the camphor solely for its stimulant effect. Since that time, however, he has used the drug regularly in all cases of pneumonia in the hope of killing the pneumococci circulating in the blood. He has used it not only in cases of frank uncomplicated pneumonia, but also for pneumococcus empyema and pericarditis. The treatment was used in twenty-one cases of pneumonia, all of which terminated in recovery. Besides this the author calls attention to the facts that in none of the cases treated with camphor was there a crisis; that a slow steady improvement began immediately after the first injection and continued with further injections; and that the duration of the illness was shortened. The camphor was administered in the form of a twenty-per cent. camphor oil in doses as large as 12 c.c. at a time, and repeated every twelve hours. Such doses of camphor given subcutaneously would seem at first sight to be distinctly heroic, but the author claims that he has had no bad results and that all of his patients have recovered. One hundred per cent. of recoveries in pneumonia is certainly a result of which one may be proud. Considering, however, that the series consists of but twenty-one cases and that they occurred during a summer service in a hospital in New York, it would be somewhat premature to accept camphor as a specific for pneumonia. The work requires confirmation on a greater number of cases during the cold season.

The Liquor Traffic and the Drug Store.

Apropos of the popular discussion on alcohol in the newspapers and magazines and the so-called "wave" of temperance reform, it is interesting to note the firm stand taken by the American Pharmaceutical Association and the National Association of Retail Druggists against the sale of liquors over the drug store counter. And this especially in view of the fact that the drug store as such is fast becoming an unknown quantity, inasmuch as very few pharmacists can earn even a fair not to say good livelihood by restricting themselves to the sale of drugs pure and simple. The temptation to dispense port, sherry, and brandy along with soaps, perfumes, and candy, in order to make business pay, has been too great, for a few pharmacists at least, to withstand; hence the resolutions passed by the two national druggists' societies. In the language of the resolutions, it is admitted that "a small minority of druggists" do a general business in the sale of liquor, while nondruggists are employing registered men to conduct saloons under the protecting cloak of pharmacy. Further, the feeling was expressed that any pharmacist or pseudopharmacist who would take advantage of temperance legislation for personal profit was a disgrace to his profession and should be ostracized by it, and a general demand was made upon the city, country, and State pharmaceutical associations to assist in carrying out the laws pertaining to sales of liquor. There may be some doubt as to the exact interpretation of the phrase "legitimate medicinal purposes," since it is by no means rigid enough to satisfy the exacting qualifications of the law. It would seem that there can be very little necessity for dispensing liquors except upon a prescription written by a physician. In fact, it may be a matter of the greatest importance to a physician who is treating inebriety, for instance, that no medicine of any kind should contain alcohol; and quite obviously the drug store ought to aid the physician in preventing the patient from procuring "a tonic" without a written order signed by the doctor in charge of the case.

News of the Week.

Harvard Dental School opens the new year in its magnificent new quarters. The new building, which is at the corner of Longwood avenue and Wigglesworth street, adjoining the Harvard Medical School, is called the finest building in the United States in structure and equipment. It is in Georgian style, and is constructed of rough water struck brick and marble. The double purpose for which the building is intended is indicated by the inscription, cut in marble over the entrance, "Harvard University Dental School and Hospital." Passing the entrance door, there is a spacious lobby, from which a marble and iron staircase leads to the upper floor. Near the entrance is an inquiry office and a telephone station. At the right of the hall is the administrative board room and the dean's office. At the left is the library and the students' room, these two rooms being so arranged that on special occasions they may be thrown together into one large assembly room. Back from the main part of the building runs a long, well-lighted wing, which, on the first floor is occupied by the prosthetic laboratory, the supply room, and the waiting-room for patients. The laboratory is equipped with the latest and most approved apparatus. The second floor is devoted largely to operative work. The infirmary, the supply room, and the waiting-room correspond to the prosthetic department below. The portion of the second floor facing Longwood avenue is occupied by the oral surgical department, and contains

two operating rooms, each with its anesthesia room, recovery room, and small ward. Closely connected with this department is a room equipped for *x*-ray work. On this floor is also a museum containing over 3,500 specimens. The dental school is connected with the buildings of the medical school by a subway, which, in addition to serving as a passage, also carries pipes from the power house of the medical school, which supply heat, compressed air, and power. The dental school building is to be used wholly for hospital purposes. The lectures are to be given in the lecture rooms of the medical school.

A Typhoid Epidemic Due to Milk is reported from Salt Lake City. The epidemic is not extensive and has been traced to a certain dealer who has been arrested for selling dirty milk. A recent localized outbreak in this city has also been traced to milk, which may or may not convince the sceptics that inspection alone is not so safe as inspection and pasteurization.

Diarrheal Diseases in Chicago.—Investigations of 130 deaths from diarrheal diseases among children under two years of age were reported by the Milk Inspectors during the week ending September 25, the summary of their observations being as follows: Thirty-four, or 26.2 per cent. of the total, had been taking mother's milk; 77 were fed cow's milk, and the other 19 were fed a variety of things from the table. Of those taking mother's milk, only one was under one week of age. Of the 77 using cow's milk, 5 had taken it raw; 18, milk heated in the home; 7, commercially pasteurized milk; 15, milk commission milk; 1, certified milk; 3, milk from town cows; 19, condensed milk, and 9, malted milk.

Train Sanitation in Michigan.—Dr. F. W. Shumway, Secretary of the State Board of Health of Michigan, has announced that he will in the near future call a meeting of the representatives of all the railways doing business in the State to discuss the provisions of the new law giving the board authority to require certain sanitary precautions on all passenger trains for the protection of the traveling public.

The Illinois Central Railroad is aranging to place individual drinking cups in all coaches of every description over its entire system. These cups will be placed in slot machines beside the water cooler, but will not displace the glass or free cups heretofore in use.

Conference of Health Officers of Iowa.—The annual conference of the State and local boards of health of Iowa will be held at Des Moines October 26 and 27. The prominent feature of the meeting will be the discussion of the new health laws enacted at the last Legislature.

Unclaimed Body Law.—According to a new law in Michigan the bodies of strangers, of those unclaimed by relatives or friends, and of those dying in prisons and public reformatories are to be turned over to certain medical institutions instead of being buried at the expense of the State.

Forced Feeding in Jail.—Legal proceeding have been instituted in England in a case of some interest to the medical profession. Several women suffrage advocates belonging to the radical suffragette party were arrested and sent to jail for disturbing conduct during Mr. Asquith's speech in Birmingham. They declared that they would not eat while in the jail, and seemed intent on starving themselves to death. Thereupon the authorities interfered and fed the prisoners by means of the stomach tube. They have begun action for assault, declaring that forced feeding is legal only in the case of the insane.

The Radium Mines of Austria.—The Austrian Government has received the entire output of the mines at Sankt Joachimsthal consisting of 154 grains of radium chloride, equivalent to 15.5 grains of pure radium. This will be distributed to the various Austrian medical and scientific institutions.

Dr. Charles J. Montgomery has been elected Professor of Hygiene and Medical Jurisdiction in the University of Georgia.

Removals.—Dr. B. Sachs of New York has removed to 135 Central Park West, Dr. Martin B. Ware to 27 East Eighty-first street, Dr. William Hanna Thomson to 70 East Fifty-fourth street, Drs. W. H. Haskin and J. G. Dwyer to 11 East Forty-eighth street, and Dr. Wm. M. Leszynsky to 145 West Seventy-seventh street. Dr. Smith Ely Jelliffe and Dr. Frederic Peterson of this city announce their return to practice after a long sojourn abroad.

The Chicago Tuberculosis Institute maintains eight free dispensaries for the treatment of tuberculosis and gives advice as to the home care of patients. These dispensaries are: Chicago Policlinic Hospital, Rush Medical College, College of Physicians and Surgeons, Jewish Aid Society, Gad's Hill Center, Northwestern University Medical School, Hahnemann Hospital, and the Stock Yards Dispensary. The Department of Health supplies tuberculin free for diagnostic purposes.

Chicago Laboratories Moved.—The laboratories of the Department of Health of Chicago, the Bureau of Food Inspection, the Recorder of Births, and the Department Statistician have moved to 218 East Washington Street.

The Opening Exercises of the Chicago College of Physicians and Surgeons were held September 28 in the college. The opening address was delivered by Dr. Wm. Allen Pusey.

The Ernest S. Lewis operating room of the Delgado Memorial Annex to the Charity Hospital of New Orleans was opened September 17. In the future all women confined to the Delgado Annex, including those with gynecological troubles, will be attended in the new room, which is thoroughly equipped.

The Children's Aid Society of New York has issued a report on its work of the summer. The Health Home at Coney Island gave outings of from one day to ten weeks to 720 mothers and 1,652 children, and day excursions to 1,652 mothers and 2,351 children; the Chappaqua Convalescent Home signalized its first season by entertaining 25 mothers and 513 children; and the Children's Summer Home at Bath Beach, which gave a week of fresh air to 4,901 children; the Boys' Camp near Stamford with 700 boys and the Martha Home at Ossining, which kept 50 little girls for ten weeks, swelled the total for the summer to 11,530. In addition to this fresh air work, the Sick Children's Mission treated more than 2,000 children in their home in the city.

Charitable Bequests.—By the will of the late Miss Phoebe Ann Thorne of New York $140,000 was given to charitable institutions. Among the bequests were $10,000 each to the following: Miriam Osborn Home Association, Rye, New York, Society for the Relief of Ruptured and Crippled, General Memorial Hospital, Children's Aid Society,

New York Skin and Cancer Hospital, and Women's Hospital; and $5,000 each to the following: New York Infirmary for Women and Children, Manhattan Eye and Ear Infirmary, New York Association for Improving the Condition of the Poor, Colored Home and Hospital, and the Society for the Relief of Destitute Blind.

The American Society of Sanitary and Moral Prophylaxis will hold its regular meeting at the Academy of Medicine, New York City, Thursday, October 14, at 8.30 P.M. The general subject for discussion will be "The Past and Future Work of this Movement."

The American Electrotherapeutic Association at its annual meeting held in New York September 28-30, 1909, elected the following officers: *President,* Dr. Thos. D. Crothers of Hartford, Conn.; *Vice-Presidents,* Dr. T. H. Cannon of Baltimore, Md., and Dr. F. E. Peckham of Providence, R. I.; *Secretary,* Dr. J. W. Travell of New York; *Treasurer,* Dr. R. J. Nunn of Savannah, Ga. The next annual meeting is to be held at Saratoga early in September, 1910.

The American Association of Obstetricians and Gynecologists at its anual meeting at Fort Wayne, Ind., September 23, 1909, elected the following officers: *President,* Dr. A. B. Miller of Syracuse, N. Y.; *Vice-Presidents,* Dr. Charles V. Smith of Toledo, Ohio, and Raleigh H. Huggins of Pittsburg, Pa.; *Secretary,* Dr. William W. Potter of Buffalo; *Treasurer,* Dr. X. O. Werden of Pittsburg, Pa.; *Members of the Executive Committee,* Drs. Wm. H. Humiston of Cleveland, Ohio, and Hugo O. Pantzer of Indianapolis, Ind. The 1910 convention will be held at Syracuse, N. Y.

The American Hospital Association held its annual meeting in Washington September 21 to 24, 1909. The next meeting will be held in St. Louis, Mo., the third week of September, 1910. The following officers were elected: *President,* Dr. H. B. Howard of Peter Bent Brigham Hospital, Boston; *Vice-Presidents,* Dr. J. N. E. Brown of the Toronto General Hospital, Toronto, Canada, Dr. Wayne Smith of the Washington University Hospital, St. Louis, and Miss Mary S. Keith of the Rochester City Hospital, Rochester, N. Y.; *Secretary,* Dr. W. L. Babcock of Grace Hospital, Detroit, Mich.; *Treasurer,* Asa Bacon of the Presbyterian Hospital, Chicago.

The Utah Medical Association at its fifteenth annual convention, held at Ogden, September 22, 1909, chose Salt Lake City as the place for the next meeting. The following officers were elected: *President,* Dr. Joseph S. Richards of Salt Lake City; *Vice-Presidents,* Dr. A. S. Condon of Ogden, Dr. Walter T. Hesler of Lehi, and Dr. E. D. Hammond of Salt Lake City; *Secretary,* Dr. W. Brown Ewing of Salt Lake City; *Treasurer,* Dr. J. N. Harrison of Salt Lake City; *Delegate to the American Medical Association,* Dr. A. C. Bailey.

The Colorado State Medical Society at a meeting held at Estes Park on September 16, 1909, elected the following officers: *Presidents,* Dr. Leonard Freeman of Denver; *Vice-Presidents,* Dr. John Espy of Trinidad, Dr. A. J. McDonald of Leadville, Dr. Ella Mead of Greeley, and Dr. Samuel C. Hadley of Fort Collins; *Secretary,* Dr. Melville Black of Denver; *Treasurer,* Dr. G. W. Meil of Denver; *Board of Councillors,* Drs. E. J. A. Rogers of Denver and George H. Cattemole of Boulder.

The Tidewater Medical Society at a meeting at Urbana, Va., September 20, 1909, elected the following officers: *President,* Dr. W. T. Jones; *Vice-Presidents,* Drs. J. W. D. Haynes, J. N. DeShazo, A. C. Palmer, and Claybrook Fauntleroy; *Secretary and Treasurer,* Dr. G. W. Brown. The next meeting of the society will be held at Saluda, June 12, 1910.

Obituary Notes.—Rear Admiral CHRISTOPHER JAMES CLEBORNE, U.S.N., died at Washington Oct. 3, 1909, aged 70 years. He was born in Edinburgh, Scotland, graduated from the University of Pennsylvania in 1860, and entered the naval service of the United States as an Assistant Surgeon in 1861. During the Civil War he served on the U.S.S. *Jamestown* from May, 1861, to January, 1862, and on the *Aroostook* from September, 1862, to August, 1863. He was promoted to Passed Assistant Surgeon on October 26, 1863, and to Surgeon on November 24, 1863; to Medical Inspector on January 7, 1878, and to Medical Director on September 18, 1887. During the Spanish-American War he was on duty in command of the United States Naval Hospital at Norfolk, Va. His last active duty was performed at the naval hospital in Philadelphia from February to November, 1899. On November 10, 1899, he was transferred to the retired list as a Medical Director with the rank of Rear Admiral. In 1886 he was chosen Vice-President of the International Medical Congress.

Dr. GEORGE EDWARD POST of Beirut, Syria, died September 30, 1909, in that city, aged 71 years. He was a graduate of the Medical Department of the University of New York in 1860, and later of the Union Theological Seminary. Dr. Post's life was given up to missionary work. As a young man he was made Professor of Surgery in the Syrian Protestant Hospital at Beirut, and later was for many years head of the Medical College of Beirut. He was also surgeon in the Johanniret Hospital in Beirut. For his work as missionary and surgeon he received the orders of the Red Eagle and Knights of Jerusalem of Germany, the decoration of Osmanich of Turkey, and that of the Ducal House of Saxony. He wrote books in several languages, on botany, zoology, physiology, surgery, medicine, and the Bible. He also published in the MEDICAL RECORD reports of a remarkable series of vesical and urethral calculi which he had removed at various times during his years of practice in Beirut. In the death of Dr. Post the missionary workers of Asia Minor lose one of their most valued leaders.

Dr. EZRA A. PALMER of Hartford, Mich., died at his home September 18, 1909, aged 62 years. Dr. Palmer was a graduate of the University of Michigan in 1876, and was one of the best known physicians in that part of Michigan.

Dr. CHARLES G. MERRILL of New Haven, Conn., died at his home September 23, 1909, aged 74 years. Dr. Merrill was a graduate of Yale University and a surgeon during the Civil War.

Dr. RICHARD W. ALLEN of Dallas, Tex., died at his home September 22, 1909, aged 68 years. He was a graduate of the Bellevue Hospital Medical College in 1872 and a member of the Dallas County Medical Society and the State Medical Association of Texas.

Dr. FREDERICK C. MCCALLUM of Hersey, Mich., died at his home September 19, 1909, aged 75 years. After graduating from the Toronto School of Medicine in 1866, Dr. McCallum went to Michigan

where he was the pioneer surgeon in the northern part of the State, practising there for over fifty years.

Dr. O. H. Evans of Springfield, Ohio, died at Jackson, Ohio, September 20, 1909, at the age of 35 years. Dr. Evans was a graduate of the Starling Medical College and a member of the Clark County Medical Society and the Ohio State Medical Association. In 1903 Dr. Evans as acting health officer had charge of the sanitary work during the smallpox epidemic.

D. Waller N. Vinal of Baltimore, Md., died at his home September 27 of pneumonia, aged 35 years. Dr. Vinal was a graduate of the College of Physicians and Surgeons of Baltimore and had served through the Spanish-American war as army surgeon stationed in Cuba.

Dr. John Janvier Black of Newcastle, Del., died at his home September 22, 1909, aged 73 years. Dr. Black was a graduate of the University of Pennsylvania in 1862 and a member of the Newcastle County and Delaware State Medical Societies and the American Medical Association, and was for many years President of the Delaware State Hospital for the Insane at Farnhurst.

Dr. John W. Coffin of El Paso, Tex., died at his home September 16, 1909, aged 43 years. He was a graduate of the Western Reserve Medical College in 1889. He served through the Spanish-American War as a major of the Tenth Pennsylvania Volunteers and had charge of the Bilibid Hospital in Manila. After the war Dr. Coffin moved from Pennsylvania to Texas and was soon appointed surgeon in the Texas Guard. He was a member of the El Paso County Medical Society and the State Medical Association of Texas.

Dr. Clifford L. Pike of Saco, Me., died at his home on September 20, 1909, aged 50 years. He was a graduate of the Medical School of Maine in 1881.

Dr. Marshall A. Gilkaith of Selma, Cal., died September 22, 1909, aged 46 years. He was a graduate of the Medical Department of the Vanderbilt University at Nashville in 1891 and was a member of the Fresno County Medical Society and the Medical Society of the State of California.

Dr. Ludwig Kohn of New York died at his home October 3, from accidental carbolic acid poisoning, aged 45 years. Dr. Kohn was a graduate of the University of Vienna in 1887 and came to New York immediately after graduation. Dr. Kohn was a member of the New York County Medical Society, the New York State Medical Association, the German Medical Society, and the East Side Physicians Club.

The Viscosity of the Blood and the Work of the Heart.—Giovanni Galli says that the molecules of the blood are subject to attrition in different individuals, due to the presence of various colloidal substances. These substances are subject to great variability, according to the amount of water in the blood and of fat molecules, and these vary with the distance from a meal. The composition of the blood varies with age, sex, and constitution. In polycythemia and plethora the viscosity is greatly increased and yet health is good. In anemia the viscosity decreases markedly. Compensation comes through the vasomotor nerves and the regulating mechanism of the heart. Increased viscosity of the blood does not produce cardiac hypertrophy. The temperature of the body, especially in febrile conditions, has also an influence on the viscosity of the blood. When with increased viscosity we have a strong heart impulse and inelastic arteries there will be greatly increased heart work, and *vice versa*.—*Rivista Critica di Clinica Medica.*

Correspondence.

SENILE PRURITUS.

To the Editor of the Medical Record:

Sir:—Recently my attention has been called afresh to a means of relief in senile pruritus which served me admirably in my practice in New York. It is so simple and so efficient that I want to recommend it to the readers of the Medical Record. In inveterate cases, after exhausting the whole line of antipruritics with very unsatisfactory results, I have found immediate and prolonged relief to follow gentle friction with a tolerably stiff hairbrush. The effect is almost magical. Not often is so much torment relieved so easily.

Andrew H. Smith, M.D.

Geneva, N. Y.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

INTERNATIONAL POSTGRADUATE ARRANGEMENTS—THERAPEUTICS OF BUDA—PHARMACEUTICAL *v.* PHYSICAL REMEDIES—TRADITIONALLY REPORTED EFFECTS—CARDIACS—ALKALIES AND ALKALINE EARTHS—THE HEALTH OF THE INDIAN ARMY.

London, September 17, 1909.

A new international organization was founded at Buda-Pest. It is called the Comité International Pour l'Enseignement Medical Complémentaire, and will be devoted to the promotion of postgraduate medical work. No less than fifteen countries were represented by delegates at the preliminary meeting, and the constitution was agreed on. An administrative committee of five members was elected, viz.: Professor Waldeyer, *President;* MM. Landouzy, Pavy, von Grösz, Kutner. There will also be a separate body—La Direction—consisting of one member from each country joining the movement. Though advantage was taken of the assembling of the congress to organize the new movement, there is no connection between the two bodies. But it will probably conduce to the success of future meetings held there at the time of the International Congresses. In the intervals there will be meetings of the Commission Administrative, which may be regarded as an executive committee. It will consist of six members, and will be the committee of the business of the Comité.

There seems to be room for the energies of such an association, and with so many eminent teachers supporting it success should be assured.

In London postgraduate work has been established on a firm basis for years. The association devoted to it made arrangements with the leading schools and special hospitals for admitting its members to all the clinical instruction given. The wards, operating theaters, mortuaries, and outpatient departments of London are therefore practically open to graduates who take out the association's ticket. Then there is also the Polyclinic, where lectures and demonstrations in all branches are constantly given, and the library and laboratory are also open for the students. Roentgen apparatus, ophthalmoscopes, and other aids to diagnosis are provided, and separate seats where a dozen patients can be simultaneously examined. The museum, too, is of great value, and contains the beautiful portraits of diseases by Sir Jonathan Hutchinson, who is the genius of the place. To him is due the unique system of consultations which take place here. To these students of the school can bring difficult or interesting cases, either for the sake of seeking the opinion of others or to serve as specimens for demonstration. Another institution is at the West London Hospital, where practical classes, ward work, and laboratory studies have been carried on for graduates during several years. The Northeast London Post-Graduate College is at the Prince of Wales General Hospital, which contains 125 beds. This college is recognized by the India Office, the Admiralty, and the universities of London and Cambridge. The London Clinical School has for many years been recognized as one of the most valuable places for instruction. It is at the Dreadnought Hospital, Greenwich, has 250 beds, and is replete with every convenience for study in the wards and the out-patients' department. The specialties are all represented. There is also an arrangement by which graduates can at the same time follow the practice of the Royal Waterloo Hospital for Women, the General Lying-In Hospital, and the Bethlehem Hospital for the Insane. These hospitals, easily accessible, thus afford the opportunity of wide experience to the students of the Dreadnought, the certificates of which are accepted by the War Office and London University.

I have said enough to show we have abundant provision for postgraduate work in London. I may add other colleges are making provisions of the kind, while for research work the universities of the three kingdoms afford opportunities and guidance.

Therapeutics, according to some reports, did not seem to excite the attention expected, either at Budapest or at Belfast, although there were excellent papers at both. At the former Dr. Colombo of Rome gave a comparative estimate of pharmaceutical and physical remedies, in which he advised that where either seemed equally suitable the physical should be selected, because its nature and effects on the human body were more familiar to us, and the effect was always alike, while remedies acting in the interior of the body through the animal fluids could not be observed in their action. However fully we understood their chemical composition and reactions outside the body, the reactions within were veiled from our tired observation and we could only judge them by inference.

This paper may very well be compared with one by Professor Dixon at Belfast, entitled "Facts and Fancies in Pharmacology." He pointed out how many supposed explanations of the action of drugs did not deserve to be so called. Tradition still attributed to remedies actions to which they had no claim. Opium had no local effect, though three preparations for local application remained in the British Pharmacopeia. Hydrocyanic acid in the doses given could not assuage gastric pain. Modern work had altogether changed our views of digitalis, which used to be thought to depress the heart. So ether and strychnine did not directly stimulate the heart. Belladonna was supposed to restrain or even arrest the lacteal secretion. It could not, as it only affected nerve endings, and the mamma had no nerves. Potash salts were called by many depressants, but this alkali was only toxic in concentrated solution, and when taken into the stomach was excreted more rapidly than it was absorbed, so that there was not much concentration in the blood. Calcium, too, was slowly absorbed and quickly excreted. Though injected subcutaneously it might rapidly increase the coagulation property of the blood in a given time. As to the action of potash, Dr. Curci has long repudiated its alleged depressing influence, and in a paper at Budapest on the physiology and therapeutics of the alkalies and alkaline earths he gave an interesting account of his researches. He went much further than a simple denial of the long received opinion, and declared that, so far from being a cardiac depressant, it has an opposite action, strengthening both the heart and vessels by a direct stimulant action on their muscular elements. Calcium, strontium, barium, thallium, cesium, and rubidium he also classed as cardiovascular stimulants. But lithium he found did not affect muscular tissue, but was a nerve stimulant. All the alkaline earths acted on nervous tissue. Calcium and magnesium might be used to reduce nervous action. But ammonium and sodium increased it.

The health of the Indian army, European and native, is the subject of a Blue book issued this week and relates to the year 1907. Apart from the prevalence of plague, which scarcely affects the statistics of troops, the year was not an unhealthy one for the general population. Among European troops the admission rates were lower than during the preceding quinquenium, lower in fact than at any previously recorded period. The native army, too, presents an equally satisfactory record, both hospital admission and death rates being the lowest recorded. Ague was the leading cause of admissions, September and October being the most malarious months. The admission rate fell to 152 per 1,000 from 176 the previous year; the death-rate from 23 to 13. The after treatment of malarious cases is now more thorough and continued for about six weeks after discharge. In many stations intramuscular injection of quinine is employed and this is said to have reduced the number of readmissions. For prevention of primary attacks in European soldiers the provision of mosquito curtains has become realized as a distinct advance.

THE SIXTEENTH INTERNATIONAL MEDICAL CONGRESS.

(From Our Vienna Correspondent.)

SERUM DIAGNOSIS—DIAGNOSIS OF CHOLERA—HIGH-FREQUENCY CURRENTS—TRANSTHERMIA—APPENDICITIS AND PELVIC DISEASE.

BUDAPEST, September 11, 1909.

In the section on internal medicine Kraus of Berlin presented an extensive report reviewing the present status of serodiagnosis from a clinical viewpoint. He said that the diagnostic value of the immunity reactions depended upon the fact that the organism was changed by infection in its relation to the infecting agent. This change could occur either as a decrease or an increase in susceptibility to the infecting substance. The humoral and cellular alteration which characterized these reactions were usually associated, though one or the other might be the more in evidence. As the specific humoral reactions occurred especially in the blood serum, they were commonly called serum diagnosis methods. The theories accepted the following hypothetical substances: Agglutinins and precipitins, practically void of protective action; complement binding substances without bacteriolytic power, antitoxins, antitoxic immunity; complement binding substances with bacteriolytic power, bactericidal immunity; and opsonins and bacteriotropins, cellular immunity. The value of antitoxins was therapeutic, and they had been of but small aid in diagnosis, though possibly the recognition of an antistaphylolysin in the blood might be an aid in the diagnosis of chronic staphylococcus disease. The antiferments were closely related to the antitoxins. Brieger had found an increase of antiferments in the blood in carcinoma, the cachexia reaction. This must be used with some care. The agglutinins were the keystone of clinical serum diagnosis. They were proved as specific for typhoid, paratyphoid, meningitis, cholera, Malta fever, dysentery, and other diseases. The precipitins, of great value in forensic medicine, in spite of the efforts of many workers, had never given results of value in clinical diagnosis. The recognition of complement binding substances followed the bacteriolytic studies of Pfeiffer, the bactericidal plate studies of Neisser and Wechsberg, and the complement fixation method of Bordet and Gengau. Pfeiffer's test served to control agglutination tests in cholera, typhoid, and paratyphoid, especially in first attacks of cholera. The complement binding reaction occurred in typhoid much earlier than the agglutination test. In epidemic meningitis, studies of the antigens and antibodies in the cerebrospinal fluid, might give a diagnosis in the absence of meningococci. The most important use of the complement binding tests was in the diagnosis of syphilis. Biologically, the Wassermann reaction was somewhat doubted, but clinically absolutely accepted. It was fundamentally a constant sign of active syphilis, and was of value in the differentiation of active and inactive syphilis, in the diagnosis of the primary lesion, in the recognition of asymptomatic and hereditary syphilis, in determining the etiology of tabes, paresis, arteriosclerosis, aneurysm, keratitis, etc., and in the diagnosis of obscure diseases. The opsonins and bacteriotropins had been applied especially in England, but were of value only when the index was exceptionally high. The nonspecific humoral reaction had been but little studied and included the improperly called "lues precipitin reaction" and "psychoreaction." The cellular immunity reaction played but a small rôle in diagnosis owing to lack of specificity, but were of preeminent importance biologically. They included the spontaneous increase of phagocytosis, the surrounding of organisms with cells, as in tubercles, actinomycosis nodules, and blastomycetic ulcers, the increase of special cells in the body fluids, as lymphocytes in tuberculosis and syphilis, pus cells in pyogenic infections, eosinophiles with parasites, etc., and the formation of Guarniri bodies in smallpox, Negri bodies in rabies, trachoma, and moluscum contagiosum bodies, all of which were efforts to wall off the infecting virus. The hypersensitive reactions, like the immunity reaction, were both cellular and humoral. Their mode of action was not clear. They were of clinical value in the various tuberculin reactions. The typhoid reaction of Chantemesse, the syphilis reaction of Neisser, and the diphtheria reaction were analogous to these, but as yet of but theoretical interest.

Dr. Paul Kaufmann of Rome presented a paper giving a new method of diagnosis of cholera. He said that if one inoculated an alkaline and consequently definitely green Jequirity-peptone solution with cholera vibrios, the media became bleached in a short time—in from four to five hours even when not more than 3 c.c. of the culture was added. The cholera vibrios shared this characteristic with various other cholera-like organisms, with the Finkler-Prior bacillus, and others. However, a negative reaction was definite proof that cholera was not present. All those who had had experience in cholera epidemics appreciated the value of such a negative test. The value of the method was increased by the fact that a thermostat was not absolutely necessary and thus the test came within the

reach of all. The test became more complex when, by the use of cholera immune serum, it was changed from a negative to a positive reaction. This was done by inoculating two tubes, each containing not more than 3 c.c. of strongly alkaline medium with the cholera vibrios. To one of these was added about 0.8 c.c. of a cholera immune serum, and the two were placed in the thermostat for six hours. The results were that in tube 1 the medium was decolorized in six hours, while in tube 2, containing the immune serum, it remained green. With all other organisms used both tubes either decolorized or remained green. The author expected to report further studies with the other organisms of the cholera group at a later date.

Dr. Nagelschmidt of Berlin read a paper before the neurological section on the subject of the high-frequency current. He had endeavored for years to give to this therapeutic method the prominence it deserved. To obtain good therapeutic results it was necessary to have a current of an especially high tension, higher than could be obtained from the majority of the instruments on the market. He laid emphasis on the especial value of bipolar applications in the production of deep action of the current. He advised their use in insomnia, melancholia, and angina pectoris. He had seen but little results from autocondensation. The use of douches in connection with the current was of especial value. He had obtained good results in neurasthenia, parasthesias, and especially with the lightning pains and crises of tabes. In some cases he obtained considerable relief and in others complete recovery from the lightning pains. Bipolar applications were indicated in the treatment of arteriosclerosis, intermittent claudication, arteriosclerotic parasthesias, myocarditis, and incontinence. The current might be applied by direct metallic or water contact; in the latter case the smallest possible amount of water should be used. By bipolar applications and the interpolation of a small spark decided muscular contractions might be produced of great service in secondary atrophies and contractures. He did not consider the high-frequency currents to be cure-alls, but on the other hand he did not believe that their action was purely suggestive, for experiments on frogs had shown that decided objective effects were observed if the current was sufficiently strong, effects not observable to the eye when the current was used on man, but none the less effective in the production of therapeutic results.

OUR LETTER FROM COPENHAGEN.

(From Our Regular Correspondent.)

NORTHERN CONGRESS ON INTERNAL MEDICINE—DIAGNOSIS OF INCIPIENT TUBERCULOSIS—TREATMENT OF PULMONARY TUBERCULOSIS BY ARTIFICIALLY INDUCED PNEUMOTHORAX—NORTHERN CONGRESS ON SURGERY—FULGURATION TREATMENT OF CANCER—INTERRUPTION OF PREGNANCY IN TUBERCULOSIS—NEW MODE OF ACCESS TO THE NASOPHARYNX—HONOR TO DR. COOK.

COPENHAGEN, September 19, 1909.

THE most important medical events since my last letter are the two congresses in which the physicians and the surgeons of Denmark, Finland, Norway, and Sweden have taken part.

The Sixth Northern Congress on Internal Medicine was held at the little watering place of the Skaw, in Denmark. The first topic chosen for general discussion was the early diagnosis of phthisis incipiens. The most interesting contribution in this section was formed by the researches of Drs. Ellermann and Erlander on sensitization of the organism occurring in the cutaneous tuberculin test (after v. Pirquet). They had found that this test sensitizes the organism in such a way that the reaction becomes stronger on reiteration of the test. Only in 8 per cent. of the cases was the second reaction a little feebler than the one resulting from the first application of the test; in 8 per cent. no difference was found, but in 84 per cent. the second reaction was the strongest. The sensitization might result in a reaction twenty or thirty times stronger than the one first obtained, and was observed even after the lapse of several months. The sensitization is not a local process, as the second application may be made anywhere on the body surface. It is not observed in an organism that is entirely free from tuberculosis.

Drs. Würtzen and Kjer-Petersen reported on their experience regarding the treatment of pulmonary tuberculosis by production of pneumothorax. Only in seven of their twenty-seven cases they had succeeded in producing a complete pneumothorax, adhesions uniting the lung with the thorax wall in the other patients. In three of the cases the treatment appeared to have been of good effect, and in one case of acutely developed phthisis they considered that the treatment had saved a life that otherwise seemed lost. Professor Langmann said he had used the treatment in forty-two cases and was on the whole satisfied with the results, the patients improving in cases in which the ordinary methods of treatment would in his opinion have failed to bring about any improvement.

During the second half of August the Eighth Northern Congress on Surgery was held at Helsingfors, Finland. Here Professor John Berg and Dr. G. Forsell opened a discussion on the fulguration treatment of cancer. Professor Berg had fulgurated during the last two years a series of cancer and sarcoma, but he believed that the fulguration in its present shape would not have any great future. As to the mode of action of the fulguration, he thought that in the treatment of small tumors a simple necrosis of both the tumor and the surrounding tissue took place. In deeply situated cancer there arose a secondary reaction of the connective tissue, resulting in a sort of strangulation of the cancerous elements. He objected to the hypothesis of a specific action on the cancer cells. Dr. Forsell agreed with Professor Berg, as also he had failed to see any beneficial effect in malignant new growths. On the other hand, he had observed good effect of fulguration in certain nonmalignant cases. For instance, several keloids had responded very well indeed to the treatment, and with a satisfactory cosmetical result.

Another interesting discussion took place on the indications for interrupting a pregnancy in serious diseases of the mother, particularly in pulmonary tuberculosis. Dr. V. Albeck said that undoubtedly a phthisis often first manifested itself or became worse during pregnancy, but he declined absolutely to interrupt pregnancy only because the woman suffered from pulmonary tuberculosis. His reasons were that it was quite uncertain whether an interruption of the pregnancy would have any good effect on a progredient phthisis—nay, it was possible that it might do the mother more harm than good. Furthermore, it might even, if rarely, turn out that a seemingly progredient phthisis became stationary during the course of a pregnancy, and finally the offspring of phthisical mothers is as a rule viable. Dr. Emil Rode took a somewhat different view of the question, and thought it right to bring about an abortus provocatus in some few cases of pulmonary tuberculosis. Where troubles arose during the pregnancy of a mentally degenerate he agreed with Maragliano, and was willing to provoke an abort, followed up by a sterilizing operation on the mother in order to free the State from the degenerate individual that would otherwise be born. Professors Westermark and Engström followed the first speaker and declined to interrupt the pregnancy under the conditions discussed.

Professor Krogens demonstrated a new method of access to the rhinopharyngeal space in operations for rhinopharyngeal fibroma, or hypophysis tumor. After division in the middle line of the lower jaw he severs the soft palate from the hard palate, and has now a very ample and easy access to the operation field.

As you have seen in the daily papers, the University of Copenhagen has honored our American confrère, Dr. Frederic Cook, by conferring upon him the honorary degree of Doctor philosophiæ. In a conversation I had with him Dr. Cook said that his expedition to the North Pole presented also considerable medical interest, and promised to return to Copenhagen and give some lectures on this part of his experiences to the profession of Copenhagen.

Progress of Medical Science.

Boston Medical and Surgical Journal, September 23, 1909.

Laboratory Work by the Country Physician.—M. A. Cummings believes that it is possible for the country physician to do more and better laboratory work than is generally imagined. Every practitioner should have a microscope with an oil-immersion lens. If the question of tuberculosis arises a man having the carbol-fuchsin and acid blue stains can in a few minutes determine the presence of the bacilli. He should always have a few culture sets for diphtheria tests in his office and from that he can make a smear to be examined with the microscope. In regard to giving antitoxin, he employs it only in those cases where the necessity is evident. He has seen urticaria and eczema follow its use, so in patients with asthmatic tendencies it is not free from objections. In the matter of examining the blood one need not be especially expert to roughly

determine the hemoglobin by the Tallquist test or the contour and relative size of the white blood cells or the presence of the leucocytes in excess by means of the Leishmann-Wright stain, which will answer also for the plasmodium of malaria. The author highly commends the text-book of Mallory and Wright. If electricity is installed in the community an *x*-ray outfit is a desideratum. Few are so separated from neighboring practitioners as not to be able to avail themselves of the neighbor's special knowledge or apparatus. The author relates a series of various cases illustrating the importance of being able to make a prompt and an accurate diagnosis of the exact condition present.

Practical Suggestions for the Life Insurance Examiner.—W. E. Porter dwells upon the advances made in the scientific work of life insurance examiners during the last few years, and attributes it largely to their mutual association for the common interests of their companies. Another advantage is the schooling which the larger companies give at their respective home offices to those physicians who are to serve them in the community at large. There are in this country some forty thousand examiners. Probably not more than two thousand of these have had any special insurance training. The author then takes up the questions of longevity, race, environment, occupation, morals, habits, use of tobacco and alcohol, family history, previous history, present condition, etc., all from the insurance examiner's point of view. Nothing new is presented, but the article is a valuable summary from the examiner's standpoint.

New York Medical Journal, September 25, 1909.

Prevention and Cure.—B. Robinson says that we fail to cure the majority of chronic cases of sickness. We simply render them more bearable and at times prevent the occurrence of certain untoward sequelæ. It is far better not to interfere too much either medically or surgically. Apart from a few specific drugs, the author is very strenuous in regard to the point mentioned. Medicines properly and very judiciously given are useful but not strictly curative agents. It is far better to endeavor to make people do what will prevent disease and render the question of operations unnecessary. We cannot as yet prevent the development of cancerous growths, but we can prevent the occurrence of appendicitis and pneumonia very frequently. The first is avoided by sensible dietary and the second by living constantly, as far as may be, in a pure atmosphere and especially by avoiding close, infected places when greatly fatigued in mind and body.

Case of Tetanus with Recovery Following Injection of Antitetanic Serum into the Sciatic Nerve.—The patient of C. M. Stinson was a male of 37 years, who developed tetanus and presented no history of traumatism. It was supposed that he had rheumatism and he was placed on a purge and salicylates. The later course of the case led to a suspicion of tetanus and close questioning revealed the fact that three weeks before he had stepped on a rusty nail, but he at once applied carbolic acid to the wound and thought no more about it. A small scar, entirely healed, was found, the former wound opened and pure carbolic immediately followed by alcohol applied. The salicylates were discontinued and 1,500 units of antitetanic serum applied, bromides and chloral being given internally. Later the dose of serum was increased and repeated. On the fourth day, as his condition seemed very hazardous, general anesthesia was given and an injection of 3,000 units was made directly into the exposed trunk of the sciatic nerve. On the eighth or ninth day a delirium developed, and as it was thought that this was due to the antitoxin its use was discontinued. On the tenth day a general roseola rash appeared, becoming brighter and lasting till the sixteenth day, when it began to disappear. In two days more it was entirely gone and was not followed by desquamation. From this time a gradual improvement ensued and the patient was discharged cured on the thirty-sixth day.

Perforating Ulcers of the Feet in Two Brothers, Caused by Productive and Obliterative Endarteritis.—The patients of W. E. Sanders were aged 48 and 46 years respectively. The older was a man of very low mentality, later becoming insane and confined in a hospital. He had frozen his feet as a boy, and at the age of 20 had his right great toe amputated at the metatarsophalangeal joint for a chronic ulcer on its plantar surface, which had resisted all treatment and led to necrosis of the bone. Healing occurred promptly, and he had no more trouble until in 1903 or 1904, when the same condition developed on the ball of the left great toe. Although the author instituted careful treatment early, the ulcer continued, necrosis of the bone of the terminal phalanx occurred, and he was obliged to amputate at the metatarsophalangeal joint. Primary union occurred except at a small point which opened down to the bone and resisted treatment for many weeks, but finally healed without necrosis of the bone developing. The stumps remained healed until about the first of May of this present year, when the left one opened again. The younger man was of unusual mental vigor. His trouble began when he was 17 with a blood blister on the ball of the great toe, which healed after three months, leaving a callus. The disease progressed with intermissions and exacerbations for a period of years, but amputation of the feet eventually became necessary. The entire duration of the disease was over thirty years, and during this whole time the general health was excellent. Unfortunately the feet removed were allowed to spoil and could not be examined. A toe taken from the older brother showed the following changes: The muscular tunic was of normal thickness and contour. The line of demarkation between the latter and the intima was well preserved. The intima in almost all of these was very greatly thickened, being in some specimens as thick as the muscularis. This thickening was of a hyperplastic character and in some cases even in these larger vessels almost completely obliterated the lumen. It was quite uniform and did not show the eccentric or new moon shaped character so commonly observed in the ordinary arteriosclerosis. The elastica interna was generally well preserved, showing that the hyperplasia was limited to the intima. Although in none of these larger vessels was the lumen completely obliterated, yet in many it was so compromised as to resemble very much the canalization so commonly observed in an obliterating thrombus. The veins did not appear to be affected. The sclerotic process seemed to be proportionately more marked in the smaller vessels, a number of which were completely occluded. In some places patulous and occluded vessels were in close proximity to each other. The adventitia and the vasi vasorum showed nothing abnormal. The author assumed the similarity of the changes in both patients, and emphasized the importance of carefully considering the vascular changes in all cases of perforating ulcers of the foot. In such nervous affections as tabes, syringiomyelia, peripheral neuritis, etc., there is no doubt of its etiology. The ulcers and trophic conditions observed in diabetes are almost always due to associated arteriosclerosis. The erythromelalgias which terminate in gangrene are most likely not neuritic entities, but rather, like intermittent claudication, due to endarteritis productiva (obliterans). Either of these conditions as well as acrosyncope or acrocyanosis immediately suggest the possibility of an underlying sclerotic condition of the vessels. It seems possible that simultaneous sphygmographic records of the pulse in the two extremities might show differences of amplitude and conduction time when only one foot is affected. The etiology of the author's cases is unknown. The vascular changes were not those of syphilitic arteritis or the ordinary senile type. Nothing was found to indicate a thromboangitis such as Buerger has described. It seems quite likely that there was a hereditary predisposition which became manifest in both cases in the period of adolescence when the growth functions were abating. Undoubtedly trauma is the important exciting factor. The results of amputation in his cases fully confirm the opinion of most authors that it should only be undertaken as a last resort.

Journal of the American Medical Association, September 25, 1909.

Rabies.—J. W. Kerr and A. M. Stimson review the data as to the prevalence of rabies in this country during the last ten years and the statistics as to its mortality. They have collected from various sources the facts for 1908, and present a map showing the reported deaths from this cause of human beings, and the outbreaks of the disease among animals. The data presented represent foci of infection actually determined, and not the number of cases among animals. The number of foci would doubtless be greatly increased, they say, if full reports from the various agricultural and veterinary institutions were at hand. Official figures were mainly used, and mere newspaper reports lacking official confirmation were excluded. The human mortality was 111, being largest in

New York, New Jersey, and Pennsylvania. In Arizona the disease was reported among skunks, and a single death of a human being from rabies reported from that territory was due to the bite of one of these animals. The most striking feature brought out by the inquiry is the very general distribution of the disease throughout the eastern portion of the country and its almost complete absence from the extreme western part. (Alaska is not shown to have been included in their inquiries.) A list of Pasteur Institutes is given and the opinion expressed that they have had a powerful influence in reducing the mortality, and since April, 1906, the United States Public Health and Marine-Hospital Service has been sending, by mail, virus to State health authorities on their request, and treating persons at a distance with satisfactory results. The authors also summarize the various State laws in regard to the prevention and treatment of the disease. They say: "To summarize briefly the results of this inquiry, there were 111 deaths in human beings from hydrophobia reported from 30 States during the year 1908. Rabies was reported in the lower animals from at least 462 localities in 39 States and Territories, including the District of Columbia. Evidence has also been secured of nearly 1,500 persons who, on account of exposure to rabies, or presumably rabid animals, were obliged to take the Pasteur treatment. The disease is disseminated throughout the eastern three-fourths of the country, and seems to have been unknown during the past year only in the Rocky Mountain and Pacific slope regions. The suppression of rabies in man is only another instance of the necessity of eliminating a like disease from among animals. This means the destruction of infected animals and the proper muzzling of all dogs in infected areas."

The Origin of Tabes.—J. J. Putnam says that, while the opinion that syphilis is the actual cause of tabes is now almost universally accepted, there still remains a certain percentage of cases for which definite proof of this etiology is lacking, and other causes are sometimes suggested. The most prominent of these is fatigue, not that which is felt, but in Edinger's sense, *i.e.* the physiological overstrain of certain portions of the nervous system carried to the point of damaging its power of nutritive repair. The questions, therefore, as to the part played by fatigue and whether or not syphilis is the sole cause are still debatable, and Putnam attempts to throw some light on them by contrasting the tabetic group of cases with another group, bearing clinically, and also as regards the location of lesions, a certain resemblance to tabes, and which, like tabes, owe their characteristics to certain toxic influences, yet which, when intimately studied, are seen to differ widely from tabes. The cases to which he refers are those presenting anatomically that form of degeneration of the nervous system which sometimes accompanies pernicious anemia, and which occur in conditions of nutritive debility not easily classifiable in one category. The nervous symptoms characteristic of these cases resemble those of tabes in affecting primarily and mainly the sensory or afferent functions of the nervous system and leading to well-marked incoordination and paresthesias, usually with loss or sometimes increase of the knee jerks. While he has seen nearly or quite a hundred instances of this disorder he has never yet encountered a single case of undoubted syphilis among them, thus differing widely from tabes and strengthening the evidence that syphilis in the latter disease cannot be merely a coincidence. The two disorders run true and maintain their special differences without overlapping or even approaching each other, and, in view of these considerations, he thinks that the argument for a special toxin or antitoxin as the essential cause of tabes, while not proved or asserted to be positive in every case, is nevertheless very strong, and deserves special recognition as a guide to treatment.

Hypophyseal Teratoma.—D'Orsay Hecht and Maximilian Herzog report a case of teratoma of the hypophysis, correctly diagnosed as regards neoplasm, but not localized, in an eleven-year-old girl. The tumor was not found at operation because of its deep location. Death followed the operation within six hours. The symptoms, which appeared first about a year before death, were disturbed vision, frontal headaches rapidly becoming more severe and diffuse, and later extending to the nape, but most acute back of the eyeballs and in the ears. Five weeks after the onset, vomiting with nausea appeared, and five weeks prior to admission to the hospital the right eye turned strongly inward and remained so. Sleep was disturbed, especially in the after part of the night, by headache, and nervous irritability was marked at times and induced by the slightest noises. Mentality was not impaired, and convulsive seizures were lacking. There was no weakness of the extremities, no general ataxia. During the last five months of her illness there was increasing aversion for food. Ear examination was negative, but there were bilateral choked discs. Only on the finer tests in a recumbent posture was there some loss of coordination in the legs. The autopsy revealed a tumor, more or less globular, with diameters, respectively, of about three-quarters of an inch vertically and about one inch fore and aft. It had corroded away the sella turcica on which it rested and was fused with and pressed on the optic commissure. It was hard, partly composed of bony tissue with complete bone structure. It was, therefore, of a mixed type, showing epithelial elements derived from the anterior portions of the pituitary body and osteoid tissue, probably derived from early embryonal occlusion. The original tumor parenchyma appeared to be formed by epithelial cells of the anterior portion of the pituitary body.

Radiography of the Mastoid Region.—S. Iglauer has employed radiography for diagnostic purposes in the mastoid region, and publishes brief notes of a number of cases thus examined, with remarks. His conclusions are stated in substance as follows: The most satisfactory Roentgen pictures can be obtained in profile, the rays centering just below the parietal eminence on one side of the skull and directed through the cranium toward the temporal bone on the opposite side, the internal anatomy of which can be thus determined prior to operation to the great assistance of the surgeon. Osteosclerosis of the mastoid secondary to chronic suppuration can usually be diagnosticated in this way, and it is likely the defects in the limits of the temporal bone will appear in the radiogram. Cases failing to heal after operation should be controlled by skiagraphy, as this may reveal the seat of the trouble. The value of the Roentgen examination in cases of acute mastoiditis remains to be determined. The article is illustrated.

Adenoids in Adults.—O. Orendorff says that we are liable to fail to recognize adenoids when they occur in a well-developed healthy adult, of age anywhere up to fifty. The following is the usual history: There was catarrh in childhood, with symptoms of nasal obstruction, perhaps following an attack of scarlet fever with prolonged recovery. During adolescence the symptoms gradually lessened, but left symptoms of chronic catarrh, of which the patient still complains. Inspection shows the usual highly arched palate with the "adenoid fringe" of its remnants, and the fauces or pharynx covered with a slimy, sticky mucus. The lingual papillæ are enlarged, and there are nodules on the posterior walls—"granular pharyngitis." In his experience, Orendorff says he has never failed to find this nodular condition high up on the posterior wall in patients over fifteen years of age. The tonsils are usually sclerotic, and the examining finger or mirror shows the disease to be more fibrous than in children, with less of the fishworm character, but invariably more voluminous than would at first appear. These patients are generally treated for catarrh and what may be called "office suggestion" until they get tired of it. In average practice there should be four or five well defined cases met with in a year. He reports and illustrates a typical case which had been overlooked by several good general physicians, and by at least one specialist of reputation. When recognized it was not relieved by the first operation, and for no other reason than that it seemed too simple to call for a careful technique. The next day the voice was still muffled and the mass in the nasal pharynx was apparently as large as before. Evidently the tumor was bifurcated and the anterior portion was pushed forward into the posterior nares at the first operation. A second operation was successful. Adenoids in adults are not common, as they usually disappear before maturity, but when they do not disappear their character changes from those of childhood. The patients are really sufferers, and there is no good in sprays, or local applications, or internal treatment. Results of complete operation are satisfactory and permanent.

The Lancet, September 18, 1909.

The Open Method of Treating Wounds After Skin Grafting for at Least the First Twenty-four Hours.—In a case in which G. W. Davis had occasion to graft over a granulating surface on the dorsum of the foot, seven small grafts from the opposite thigh were placed directly on the surface of the granulation tissue, and instead of the usual dressing of tinfoil, etc., no dressing of any kind was applied, but the foot and leg were protected by a wire gauze meat-cover, cleaned with methylated spirit and having an opening made to include the leg. The wound was prevented from becoming dry by dropping a saline solution upon its surface. The seven grafts took well, and

appeared to him to be more vigorous than usual. It would be quite easy for any of the leading instrument makers to make wire covers in various shapes suitable for any part of the body and bearing at their upper part a small, flat tank having a capacity of four fluid ounces and covered with asbestos to maintain the warmth of the fluid. A tube of flexible metal would enable the saline fluid contained in the tank to be directed on to the wound, and a tap would control the rate of flow. A layer of cellulose dressing backed by a piece of mackintosh would be amply sufficient to absorb the overflow. The temperature of the part in winter could easily be maintained by a little arrangement to that end.

Peau d'Orange in Acute Mammary Cancer; Its Cause and Diagnostic Value.—A. Leitch objects to the view advanced by Astley Cooper that the pitting and general "orange-skin" appearance in acute mammary cancer is caused by the contraction of the fibrous tissue in the tumor acting through the suspensory ligaments. It is rather caused by the same factors suggested by the identical appearance in the skin of the arm in the "brawny arm of breast cancer." The lymph stasis of the arm is due, not to the compression of the axillary veins, but to the blocking of the lymphatics of the permeating growth. The depressions of the surface giving the orange-skin appearance are the exaggerated pits of the hair follicles. The erector pilæ has its fibers separated like the rest of the corium. In a word, the thickening of the skin is due to changes in the corium. These changes are the result of lymphatic permeation and consequent lymph stasis. The corium is expanded and the overlying epithelium is raised above its normal level by the pressure, except at those places where it is bound down by the insertion of a hair follicle in the corium, where it is, as it were, moored. Taking into consideration the cause, already known, of pitting in the brawny arm and this same explanation already advanced for the similar condition in the breast, it seems reasonable to argue that when we get the condition it must be due to lymph stasis caused by the blocking in the lymphatics. There is no disease in the breast at all likely to produce this condition other than cancer. Thus, even in the absence of other signs, a diagnosis of acute mammary cancer from this alone would be practically certain. The author confirms his views by the result of microscopical examination of the affected skin.

The Temperature as a Guide to the Treatment and Prognosis of Phthisis.—S. V. Pearson emphasizes the necessity of a close study of symptoms in each individual case. This is notably true with regard to temperature. It is recognized (1) that with a miliary tuberculosis it is usual to find a type of temperature continuous or inverse; (2) with an acute caseating lesion a remittant or markedly intermittent type is found; (3) with a chronic fibroid lesion, constantly normal or subnormal is the rule, while (4) with a chronic fibrocaseous lesion either a normal, subnormal, or an elevated temperature is found, according to the state and stage of the disease. The author then passes to consider the method and time of taking temperature and the interpretation of the readings. There is, he says, no such a thing as a normal temperature, unless we take into account the natural daily curve, and in making daily comparisons estimate every attending circumstance, as exercise, diet, etc. He then takes up the peculiarities of temperature in women with reference to menstruation, touches on rare and ambiguous cases, discusses regulation of rest and exercise, and instability and lack of elasticity in temperature. In treating tuberculosis we should always remember the object we have in view. All cases cannot be arrested. We must take a chance with prolonged rest under suitable conditions. The rest must be very complete when the temperature is high and must be continued as long as there is the slightest trace of fever. The patient must be carefully taught how to avoid relapses.

British Medical Journal, September 18, 1909.

Oral Sepsis with Peculiar General Symptoms.—C. W. Smith and A. E. Barnes report the case of a man of 35 years who began to have symptoms which were supposed to be rheumatic as he had the usual arthritic evidences, followed by profuse sweating. A succession of attacks occurred so regularly as to make it necessary to exclude malaria, but he had never been in a malarious district, parasites were absent from the blood, and quinine systematically given did not avert the attacks. A heart murmur appeared during the latter, and naturally infective endocarditis was feared. The definite signs of organic cardiac disease did not appear, and blood cultures were negative. There was erythema combined with the joint symptoms, but the skin lesions were never purpuric, and there were never any visceral symptoms. So the existence of any of the erythemata allied to Henoch's purpura was excluded. When the authors had excluded all other infections they considered the condition of the teeth, some of which were carious and some artificial. It was subsequently learned that a few weeks before the patient's illness he had had his artificial dental plate readjusted and found it uncomfortably tight, but continued to wear it. The quartan occurrence of the attacks could not be accounted for. It suggested infection by some protozoan having a definite life cycle. The carious roots were extracted, but unfortunately not examined. The authors say that if oral sepsis was the cause of the symptoms in this case it becomes of great interest in view of the recent attempts to show that various rheumatic affections are really the result of oral sepsis, a view which they think has much to support it.

Apparently Acute Simple Febrile Erythema Associated with Subsequent Smallpox.—The patient of D. S. Davies was a girl of 16 years who began to have sore throat, fever, headache, and a profuse, soft, papular rash, scattered over the entire body, being most marked on the front and outer side of the upper arm. She was admitted to hospital for observation. Later the rash showed as a deep, dusky erythema, there being no development of the papules. The stomach and bowels were cleaned out and all acute symptoms subsided. The erythema faded away and was followed by a branny desquamation. At no time did even a single papule suggest the most modified or abortic form of the true variola papule. Some time later her brother, with whom she had been spending her convalescence, developed semi-confluent smallpox and recovered, and two days later her father came down with the hemorrhagic variety, from which he died. Later the girl was reexamined, and discoloration was found persisting over the spots where the erythema had been. The association of the three patients raises in the author's mind whether the febrile erythema may have been a manifestation of smallpox in the patient's system. The dull color of the immature papular rash, its failure to form a true papule, and the subsequent dull and persistent staining suggested what is almost a contradiction in terms—a benignant hemorrhagic attack. If this is possible, as it may be in the case of a singularly searching and virulent infection acting upon a highly resistant individual, the case is worthy of record.

Treatment of the Small Intestine in Operations for Intestinal Obstruction.—C. H. Whiteford says that in a patient almost *in extremis* the actual obstructive cause has to be neglected and an enterostomy, that is, the opening and draining of the first distended coil which presents through a small median abdominal incision, is all that is justifiable, and may give the patient a fighting chance. In a patient who can stand a general anesthetic the surgeon must (1) evacuate completely from the distended bowel the quarts of liquid which are poisoning the patient and are paralyzing and causing a succession of partial kinks in the intestinal walls, and (2) restore the potency of the intestinal tract by either removal of the obstruction or, if this is impossible, doing a short-circuiting operation. Details of the latter procedure are given. The following conclusions are emphasized: (1) Excluding those cases which are nearly moribund and in which an enterostomy is all that is justifiable, it is essential that the operation should, in addition to relieving the intestine, empty the small intestine of all poisonous contents, and (2) the most efficient and rapid method of emptying the small bowel is to adopt Moynihan's plan of threading them on a straight tube.

Münchener medizinische Wochenschrift, August 31 *and September* 7, 1909.

Experiments with Intraarterial Anesthesia.—W. A. v. Oppel has carried out a series of experiments in the intraarterial injection of cocaine in animals to find the toxicity of the drug. He found that the poisonous symptoms appeared in inverse proportion to the area of distribution of the vessel into which the drug was injected. An animal would stand twice the dose in the aorta that it would in a femoral. Injection into the carotids was no more dangerous than into a peripheral vessel of the same size. Tying off the carotid, however, so as to cause the drug to shunt through the vertebral arteries into the medulla caused a great increase of toxicity. Subcutaneous injections were two to three times less dangerous than intraarterial and fifteen to twenty times less than intravenous.

A Form of Skin Tuberculosis Among Coal Miners.—Fabry, as the result of twenty years' observation among

the coal miners of Westphalia, reports on the observation of 255 cases of a peculiar and characteristic skin disease which occurs on the back of the hands, fingers, and extensor surface of the forearms of the miners characterized by a warty growth, which microscopically resembles a tuberculide rather than a true tubercle, a small celled infiltration, usually without migratory cells. On the other hand the cases give positive reaction to old tuberculin and are liable to scrofula. The condition is a true occupation malady, due to the excoriation on the hands of the miners. The explanation of the mild character of the disease is that the finely divided coal dust in the wounds tends to weaken the virulence of the tuberculous virus.

Cyst Formation in Appendical Remains.—Stubenrauch points out the fact that occasionally following attacks of appendicitis, whereas the middle portion of the organ becomes gangrenous and sloughs, the tip remains intact, and if the blood supply remains secretions continue and the result is the formation of a cyst. He reports several such cases in which at operation this cyst closely resembled a lymph gland. Hydrops, empyema, or cyst formation could occur in the bit of tissue. In every case of recurrent appendicitis, especially when the appendix stump is short and bound down, such a cyst should be sought, and, if found, removed.

Serodiagnosis of Echinococcus Infection.—Kreuter says that whereas echinococcus cysts can as a rule be diagnosed by a puncture and examination of the contents, cases occur in the brain and in the abdomen where puncture is not possible. Recently an increase of the eosinophiles has been shown to be a valuable symptom of this infection. As, however, the eosinophilia also occurs with many other parasites, it is far from a sure diagnostic sign. The author has therefore investigated the hemolytic reactions of the blood in such cases in the hope of finding a specific complement binding reaction. As antigen he used the fresh fluid from echinococcus cysts, watery extracts of the dried cyst contents, and alcoholic extracts 1 to 20 of the cyst contents. For the amboceptor he used the serum of the patients and controls inactivated at 56° C. For complement fresh guinea pig serum in five per cent. solution was used. He reports the results of his investigations in the form of tables, and concludes that fresh hydatid fluid causes a complement binding in the serum of persons suffering from echinococcus disease; that an alcoholic extract of the dried contents of the cysts gives a similar reaction, but a watery solution does not, while normal serum does not prevent the hemolysis. The researches were confined to two cases, and the author says further investigations are needed to confirm the specificity of the reaction.

Histological Researches of Hypertrophied and Insufficient Heart Muscle.—Lissauer has carried out a histological investigation into the relation between hypertrophy and weakness of the heart muscle. The most noticeable things were the changes in the nuclei of the heart muscles. These were of three kinds, (1) the ridged or lamellar nucleus in which concomitant ridging and flattening occur. The ends of the nucleus are not rounded, but appear to be cut or broken off; (2) the swollen nucleus with decrease in the chromatin; and (3) a nucleus with abnormal lengthening and thickening of the chromatin. Fragmentation has never been proven to be the cause of weakness in the hypertrophied heart. Longitudinal segmentation was observed in a few cases. Vacuolization was also seen in a considerable number of the cases. Fatty degeneration occurred with especial frequency but to only a mild grade. Deposits of round cells were especially rare, while increase in connective tissue was very frequently found. These are probably the result of anemic necrosis. Besides the isolated islands of scar tissue increase in interstitial connective tissue was found probably dependent upon congestion. The author considers all the above pathological changes to be the result, not the cause, of the cardiac weakness.

Further Studies of Scarlet Red and Its Components on Granulations.—Hayward discusses the use of scarlet red ointments in the treatment of open wounds. He then describes his efforts to find the active principle of the scarlet red. Scarlet red is a compound consisting of one molecule each of β-naphthol and amidoazotoluol. An 8 per cent. ointment of amidoazotoluol was placed on the wounds for twenty-four hours and then followed for from one to two days by an indifferent ointment, as vaseline. The results were quite as good as with scarlet red, old wounds granulating rapidly. The amidoazotoluol is a reddish brown powder with a melting point of 100° C. It is insoluble in water, easily soluble in alcohol and ether.

Agglutination for Typhoid in Infection with Gärtner's Bacillus.—Rimpau studied a series of 97 patients poisoned by eating meat infected with *B. enteriditis Gärtneri*, and found that the serum of these patients agglutinated the typhoid bacillus, and *vice versa* the serum of typhoid patients agglutinated the Gärtner bacillus, though that of partyphoid cases did not. This fact is of importance, as the illness from the Gärtner infection is of short duration, but, beginning with acute abdominal symptoms, may easily be mistaken for typhoid fever.

Epidemic of Gonorrhea Among School Children in a Salt Bath.—Bendig reports an epidemic of gonorrheal vaginitis occurring among a crowd of school children sent off to a "saltbath" in the summer. The children bathed two at a time, and those two used a common bath towel. One little girl was infected with the gonococcus, and as by the method of pairing the children for the bath the mates changed each day, the infection spread rapidly to fourteen of the forty children. Permanganate irrigations and organic silver instillation were used in treatment. The author advises as prophylaxis careful supervision of the children and examination at least once a week by a physician of each child during its visit, and on admission not later than the second day. To prevent the spread of contagious diseases the children should also be examined on the day of departure. Each child should bring its own towel, bearing the child's number. These should not be used by any but the owner. More than two children should not be bathed in the same water. During the dressing the overseer should investigate for signs of contagious disease, and if anything suspicious is seen it should be referred at once to the house physician. Each child must have its own bed and use it exclusively. The bedding should be examined carefully daily for signs of disease. The overseer must see that the children do not get into bed together. Contagious diseases must be reported immediately to the house physician.

Deutsche medizinische Wochenschrift, September 2, 1909.

Sources of Error in the Turpentine-Guaiac and Aloin Tests for Blood.—Adolf Ohly discusses these methods of testing for blood in the stools, and lays stress on the following points: The turpentine oil must always be old and well ozonized. This is obtained by allowing the bottle to stand open to the air in direct sunlight. The reaction depends upon a catalytic action on the blood derivatives, which occurs in the presence of ozonized turpentine or peroxide. The ozone acts as a catalyzer and is not changed by the reaction. It is of especial importance that in the shaking of the stool emulsion the test tube be well stoppered with cotton, so that the finger shall not come in contact with the material, as the amidoacids in the sweat may give a positive reaction with the guaiac test. The alcoholic solution of guaiac and aloin must be completely dissolved before it is used. The specimen of stool must be very thoroughly rubbed up with water and glacial acetic acid in order that the smallest particles may be reached by the acid. In using the test one must be careful to rule out hemorrhoids and also a diet containing flesh or blood, as a small particle of undigested meat may give the reaction.

Tuberculin Antibodies During Specific Treatment.—Pickert says as the result of a series of experiments that the tuberculin neutralizing material previously described by himself and Lowenstein as occurring in the course of the specific treatment of tuberculous patients with tuberculin is a tuberculin antibody in the narrowest sense of the word. After the injection of a large dose of tuberculin they observed the same regular phases in the antibody content of the serum as occurs in other immunizing processes, as diphtheria or tetanus. There is unquestionably a definite parallelism between a spontaneous high tuberculin antibody content and a favorable course of the tuberculosis. From this it results that dependance upon the antibody curve is a necessary therapeutic procedure in order that, at least when large doses are being injected, the antibody content of the serum be kept at a level most favorable for the organism.

Physiological Osteoid in the Fetus and New Born.—Wieland concludes from a series of investigations that the youngest uncalcified bone deposits which Pommer first described as occurring in varying places in infants, children, and adults are present constantly in increased amount in the bones of the new born, and the earlier in fetal life the greater their extent. In contradistinction to the variations in the distribution of these deposits, their thickness is fairly constant, and rarely exceeds 8 to 12 microns.

Book Reviews.

Suture of Arteries. An Experimental Research. By E. Archibald Smith, M.B., Ch.B., Victoria University. F.R.C.S., England. London: Henry Frowd, Hodder & Stoughton, 1909.

This small volume begins with a history of the suture of wounds in arteries, giving a list of published cases in human surgery. The development of the method of end-to-end anastomoses is presented, after which the author describes his own method. He agrees with others that the endothelial surfaces should be brought together, and he accomplishes it by means of the "U" or mattress suture, which is modified into a figure-of-eight suture by means of a short piece of catgut; this is passed through the loops of the mattress suture on each side of the wound, thus creating the maximal endothelial contact with the minimal amount of thread inside the lumen. The best part of the author's work is a histological study of the healing process in the vessel walls. The sections from the experiments are described according to the length of time healing was allowed to go on, the first specimen being examined histologically two and a half days after suture, while the last one was prepared fifteen weeks after operation. He concludes that a *restitutio ad integrum* of the vessel wall may occur.

Klinik und Atlas der chronischen Krankheiten des Zentralnervensystems. Von Professor Dr. August Knoblauch, Direktor des städt. Siechenhauses zu Frankfurt a. M. Mit 350 zum Teil mehrfarbigen Textfiguren. Berlin: Verlag von Julius Springer, 1909.

This is a quarto publication of 608 pages and 350 illustrations, many of the latter in color. The general appearance of the book is attractive, and a careful study of the text and illustrations shows excellence in both. The illustrations are placed for the most part in the text, which also contains in detail the explanations. In such a difficult department of medicine as neurology, a suitable atlas provides us with a short cut, as it were, to an accurate understanding of the subject and is second only in usefulness to actual demonstrations by specimens and patients. In this instance, we have a series of clinical lectures on patients affected by the various types of chronic organic nervous disease drawn from the author's twelve years' observation at the Municipal Infirmary at Frankfurt-on-the-Main. There is no attempt to produce a text-book, apparently; but, accompanying the descriptions of cases, we find their photographs, various explanatory drawings, and such charts and classical pictures and microphotographs, etc., as a clinical lecturer might employ to illustrate his lecture before a class of advanced students. The only so-called functional nervous diseases included in the book are epilepsy (now usually classed as an organic disease) and hysteria. Treatment is not touched upon. The author makes special acknowledgment in his preface to Brissand, Edinger, Erb, Hermann, von Monokow, Retzius, and others, for plates, etc., taken from their more recent works; and a full list of authorities quoted or furnishing plates is given at the end of the book. In the latter we do not find any American names. The author employs German names in his original drawings and figures, instead of the customary, and, we think, preferable method of using the universal Latin terms. We were especially interested in the articles on alterations of the pupil in various nervous diseases and the illustrations pertaining thereto. As to the utilization of various up-to-date accessory methods and phenomena in diagnosis, the author is ultraconservative.

Myomata of the Uterus. By Howard Kelly, Professor of Gynecology in the Johns Hopkins University; Gynecologist-in-chief to the Johns Hopkins Hospital; and Thomas S. Cullen, Associate Professor of Gynecology, Johns Hopkins University; Associate Gynecologist to the Johns Hopkins Hospital. Illustrated by August Horn and Hermann Becker. Philadelphia and London: W. B. Saunders Company, 1909.

This valuable work is the result of over ten years of study of the material seen at the Johns Hopkins Hospital. One thousand six hundred and seventy-four cases of uterine myomata have been examined and treated by the authors. The history of each patient was carefully scanned for special points of interest, complete descriptions of the gross and histological appearances of the tumors were made, accurate and detailed illustrations, the work of Horn and Becker, were drawn in the majority of instances. Finally, the results of these researches were used to classify the interesting features of the cases which were gathered under thirty-five different headings that form the titles of as many chapters in the book. It is barely possible to note the main points of interest, brought out by the authors, within the limits of this review. In the chapter on parasitic uterine myomata the endless variety in size, attachment, and blood supply of these tumors is strikingly shown by records and illustrations of actual cases. Hyaline and cystic degenerations and calcification of myomata are considered, the latter of these changes being traced to lack of blood supply and the action of toxic substances formed in the myomatous tissues; the urgent necessity of operating in cases of suppurating myomata is thoroughly accentuated. Of great interest is the study of malignant changes in these benign uterine tumors. About six per cent. of the cases showed adenomyomatous changes at the time of operation; in over one per cent. sarcomatous changes were present, the actual ratio probably being much higher, the difficulty of finding a beginning change of this sort in a large specimen being self-evident. In two per cent of the patients adenocarcinoma was found in association with the benign tumors. The effects upon other organs is treated at length, the tubes, ovaries, kidneys, ureters, bladder, and intestine being described and pictured from a great number of cases. The influence of race is shown by the interesting fact gleaned from the study of a thousand autopsies that the uteri of thirty-three per cent of colored women contained myomatous nodules, while only ten per cent. of white women were so affected. In addition to the pathological studies sufficient attention is paid to the clinical side, the symptomatology and the differential diagnosis being fully considered. Operative technique is discussed, the vast experience of the authors who have succeeded in bringing down their operative mortality to less than one per cent. being a guarantee of the practical usefulness of this discussion. The book is provided with a complete index, containing abundant cross references.

Hydrotherapy, a Brief Summary of the Practical Value of Water in Disease, for Students and Practicians of Medicine. By William H. Dieffenbach, M.D., United States Delegate and Vice-President of the First International Congress on Radiology and Ionization at Liege, Belgium; former Professor of Bacteriology, New York Medical College and Hospital for Women; Professor of Hydrotherapy, New York Homeopathic Medical College and Flower Hospital; Physical Therapeutist to Volunteer St. Gregory's Hospital; Electro-Therapeutist to Flower and Hahnemann Hospitals; member of the National Society of Physical Therapeutics, American Electro-Therapeutic Society, New York Physico-Therapeutic Society, American Roentgen Ray Society, American Institute of Homeopathy, Academy of Pathological Science, etc. New York: Rebman Company, 1909.

This volume contains the author's yearly lectures on the subject of hydrotherapy, and is a valuable addition to the literature of this important branch of therapeutics. The first part of the work contains chapters on chemical and physical properties of water, physiological effects of water, principles of cure involved in hydrothermotherapy, the technique and indications of the principal hydrotherapeutic procedures, the half bath, the full bath, the sitz bath, the foot bath, the hand bath, douches, affusions, ablutions, packs, compresses, bandages, foments, ice bags, ice compresses, coils and tubes, Turkish and Russian baths, etc. The remainder of the book is taken up with the practical applications of hydrotherapy to the various diseases. The first part of the work is of considerable value, and the illustrations are artistic and serviceable. The author gives the results of his own experience; and he also gives due credit to other workers in this branch of therapeutics.

Human Physiology. An Elementary Text-Book of Anatomy, Physiology, and Hygiene. By John W. Ritchie, Professor of Biology, College of William and Mary, Virginia. Illustrated by Mary H. Wellman, Yonkers-on-Hudson. New York: World Book Company, 1909.

This is one of the most satisfactory school books on this subject which we have seen. The text is well balanced, containing sufficient anatomy to make clear the broad outlines of the structure of the human body, and enough physiology to make plain the great laws according to which the body lives. The sections on hygiene are particularly well done, and the parts dealing with alcohol and tobacco are replete with scientific facts, instead of being a mixture of sentiment and ignorance, as is too often the case. There are numerous illustrations, and the type and size of the book are all that can be desired. Both teachers and pupils will find this book one of unusual interest, as it most certainly is one of unusual merit.

Society Reports.

AMERICAN GASTROENTEROLOGICAL ASSOCIATION.

Twelfth Annual Meeting, Held at Atlantic City, N. J., June 7 and 8, 1909.

(Special Report to the MEDICAL RECORD.)

Monday, June 7—First Day.

THE PRESIDENT, DR. JULIUS FRIEDENWALD OF BALTIMORE, IN THE CHAIR.

President's Address: The Development of Gastro-Enterology in America.—DR. JULIUS FRIEDENWALD of Baltimore, in his opening address, traced the development of gastroenterology in America, and reviewed its most important achievements from the beginning of the nineteenth century to the present day. (See page ??.)

Catheterization of the Pylorus and Duodenum.—By Dr. MAX EINHORN of New York. (See page ??.)

On Duodenal Ulcer and Its Treatment.—Dr. MAX EINHORN of New York said that formerly duodenal ulcer was looked upon as a rare disease, which could scarcely be recognized during life. When chronic ulcers of the stomach began to be treated surgically, duodenal ulcers were often met with at the operation, and it was shown that in many cases in which the ulcer was believed to be in the stomach it was found in the duodenum. Until recently, a positive diagnosis of duodenal ulcer could be made only on the operating or post-mortem table, as the clinical symptoms were not sufficiently marked to indicate the condition with certainty. Since using the thread test, Dr. Einhorn said, he believed that the diagnosis of duodenal ulcer could be made clinically with some certainty. The author then reported in detail six cases of duodenal ulcer in which the diagnosis was made by this test. In four, the symptoms pointed to duodenal ulcer with some probability; in two, however, they were in no way characteristic. In all of the six cases a marked hyperchlohydria was present; in two there was slight continuous hypersecretion of gastric juice. Slight peristaltic restlessness of the stomach was found in only one case. Pain was generally present two or three hours after meals, and was alleviated by the ingestion of food. Moynihan called this symptom hunger pain. In nearly all the cases, periods of suffering alternated with periods of perfect euphoria. Hematemesis or melena was found in two of the cases. Constipation was usually present, but a tendency to diarrhea was found in two. Pain on pressure was absent in nearly all of the cases. The symptoms above enumerated (excepting hemorrhages) were all caused by hyperchlorhydria, and frequently occurred without the presence of duodenal ulcer. If, however, in association with the above symptoms, hemorrhages in the digestive tract occurred, the diagnosis of duodenal ulcer was justified. Gastric ulcers generally acted differently, giving rise to pain immediately after meals, to pressure pains in the epigastrium, etc. The diagnosis became more positive if the thread test showed a distinct blood spot at a distance of 58-60 cm. from the teeth. Discussing the treatment of duodenal ulcers, Dr. Einhorn said it should first be medical. In the mild cases it should be limited to a regulation of the diet and an improvement of the general condition of the patient, together with cold sponging, the avoidance of bodily exercise, and the use of alkalies. In several cases olive oil seemed to be of service. In graver cases, with hemorrhage, severe pain, etc., a strict ulcer cure, with rest in bed and rectal alimentation, followed by a fluid diet, must be instituted. In these cases, large doses of magnesia and bismuth were of benefit. If a strict rest cure proved unsuccessful, or if we had to deal with severe hemorrhages, endangering life, or if obstinate spasm of the pylorus occurred associated with severe pains in the pyloric region and slight peristaltic restlessness of the stomach, an operation (usually gastroenterostomy) was indicated. In these cases the operation, fortunately, was usually attended with good results. The ulcer soon healed, as the gastric juice no longer flowed over the ulcerated surface in the duodenum to irritate it, and at all events the dangers of hemorrhage, perforation, and pyloric stenosis were thereby prevented. In duodenal ulcer the clinician must advise surgical treatment sooner than in gastric ulcer, as the former, through its complications—hemorrhages, perforation, and stenosis of the pylorus—endangered life much more readily than the latter.

The Relation of the Islands of Langerhans to Glycosuria.—Dr. W. G. MACCALLUM of Baltimore said it had for some time been a disputed question as to whether the islands of Langerhans alone or the whole tissue of the pancreas were to be looked upon as controlling carbohydrate metabolism, and in order to determine this, if possible, the following experiment was carried out: A portion of the pancreas of a dog was separated from the rest, and its duct ligated. Under such circumstances, the ligated portion underwent atrophy, presumably only the islands of Langerhans escaping the injurious effects of the ligation. Six months later this part of the pancreas was found to be scarcely visible in the mesentery, and at that operation all of the intact portion was removed. The dog then had no secreting pancreas, and was limited to the small fragment presumably containing only islands of Langerhans, and remote from the intestine. After temporary glycosuria and steatorrhea, the dog became able to assimilate fats and carbohydrates nearly as well as a normal dog. The small remnant was then removed, and there immediately resulted an intense glycosuria On section, this remnant was found to consist of distorted tissue, apparently identical with the tissue of the islands of Langerhans, although the masses were increased in bulk beyond that seen in the normal pancreas. The experiment was of interest chiefly in that it seemed more exact than those in which, after ligation of the main duct of the pancreas, there was no glycosuria.

Physiological Aspects of Gastroenterostomy.—Dr. W. B. CANNON of Boston said that the purpose of performing gastroenterostomy was to render the emptying of the stomach into the small intestine possible if the pylorus was closed, or more rapid if there was delay in the passage of food from the stomach. In either case it was assumed that there was a change in the course which the food took in passing from the stomach into the bowel. Two questions of physiological interest might arise with regard to the effect of an artificial opening between the stomach and the small intestine. Under what conditions did this new opening induce an alteration in the course of the food? If the normal course of the food was changed, what were the results of that change? The only power which could carry food forward from one part of the alimentary canal to another was that greater pressure existed behind the food than existed in front, and this pressure was ordinarily exerted by the peristaltic wave. The result that followed from the greater fluidity of the food near the pylorus and the greater pressure upon the food at that point was that the chyme took its normal passage through the pylorus, if the pylorus was patent, rather than through an artificial opening. This fact was first determined by Kelling, who performed gastroenterostomy by all the methods known to surgery. He observed that nothing left the stomach by the new opening; all food, whether solid or liquid, emerged by way of the pylorus, as could be determined through the duodenal fistula. This observation was confirmed in *x*-ray studies by the author and by Blake, and likewise supported by Maury, who traced the course of the food by means of strings attached

to little bags containing lead shot. On the basis of these observations Moynihan concluded that gastroenterostomy was most effective only when gross mechanical obstruction existed, and that under no circumstances should it be done in the absence of demonstrable organic disease. If gastroenterostomy was performed when the pylorus was entirely obliterated, the new opening presented the only outlet from the stomach, and under those circumstances the mechanism operating normally in the duodenum might become to some extent impaired. The effect of acid chyme in causing a flow of pancreatic juice and bile was now a well-known physiological fact. With the pylorus closed and the stomach as the only exit, one might suppose that the admixture of the chyme with the pancreatic juice and bile would be largely abolished, but that need not necessarily be the case, and it was altogether probable that a certain amount of pancreatic juice and bile was carried into the jejunum and ileum, and there mixed with the food.

The Immediate Results and Surgical Complications of Gastroenterostomy.—Dr. Fred T. Murphy of Boston discussed this phase of the subject. He said that as the one definite indication for gastroenterostomy we had some obstruction to the passage of food from the stomach to the small intestine. As a possible indication for gastroenterostomy we had the effect of the operation upon the gastric secretion. Analysis of the stomach secretions after gastroenterostomy showed that the acidity was diminished, either by neutralization from the alkaline secretion of the duodenum, or by some reflex carried by the blood stream. The keynote of recent symposiums on the surgery of the stomach had been to operate only when some actual lesion of the stomach or duodenum could be demonstrated. Gastroenterostomy for undemonstrable lesion of the stomach or duodenum had been a failure. In perforation of the stomach or duodenum, gastroenterostomy, a few years ago, was a universal procedure; it was now advised only when the closure of the ulcer might cause obstruction. The operation upon the ulcer itself, either by infolding or excision, was the essential feature. Gastroenterostomy, in its development, had seen many phases, and as the universally adopted operation we now had the no-loop posterior gastroenterostomy, done with suture and with clamps. The anterior operation remained only as one of necessity. The innumerable mechanical devices which had been brought forward to meet the supposed technical difficulties were now used as routine only by their enthusiastic originators or by surgeons of little experience. In speaking of the possible complications of gastroenterostomy, Dr. Murphy mentioned infection, vicious circle, hemorrhage, peptic perforation, pneumonia, obstruction due to adhesions or to infolding of the mucous membrane, contraction of the anastomosis and hernia through the slit in the mesentery of the transverse colon. They were for the most part but ghosts of the past. Peptic perforation remained as a very rare but apparently unpreventable complication. The vomiting of the so-called vicious circle, once a very distressing and frequent complication, might be considered as an evidence of some obstruction to the passage of the stomach contents into the jejunum. With only partial obstruction the case could be relieved, as a rule, by stomach lavage.

The Clinical Results of Gastroenterostomy.—Dr. H. W. Bettmann of Cincinnati and Dr. F. W. White of Boston, in a joint paper, discussed this phase of the subject. (See page 598.)

The Results of Operations for Malignant Diseases of the Stomach.—Dr. J. M. T. Finney of Baltimore read a paper on this subject, in which he emphasized the following points for consideration: 1. The importance of the earlier recognition of cancer of the stomach by medical men. 2. The importance of turning them over to the surgeon soon after recognition. 3. No medical nor serum treatment should be depended on; surgery was the only hope. 4. Surgery, to be effective at all, must be applied at the earliest possible moment. 5. Our most fruitful effort lay along the line of the prevention of cancer rather than cure.

Dr. Joseph C. Bloodgood of Baltimore said it seemed to him that gastroenterostomy, with our present technique, was an operation that could do no harm. While those who had studied the subject from a purely physiological standpoint might not agree with him, he thought that all surgeons, even those whose experience in surgery of the stomach was somewhat limited, felt that a properly performed posterior gastroenterostomy, with a short loop, had no complications.

Dr. Max Einhorn of New York said he agreed with those who would limit this operation to those conditions where there were strong indications for such a procedure, principally obstruction of the pylorus. With regard to cancer, he also agreed that the earlier we could make the diagnosis and the earlier the operation the better. That view, he ventured to say, was held by almost all physicians, but one practical difficulty we had to contend with was that the diagnosis was not easy and could not, as a rule, be made very early—even for two or three months after the onset of the disease—because the symptoms of early cancer of the stomach were frequently very obscure.

Dr. C. G. Stockton of Buffalo said he wished to enter a mild protest against the position taken by one of the speakers as to the innocuousness of gastroenterostomy. He would exclude from this category those cases in which it was undertaken for the relief of mechanical obstruction. He agreed with Dr. Einhorn in regard to the comparative infrequency of cancer of the stomach following upon previous ulcer.

Dr. Franklin W. White of Boston said that in the paper which had been prepared by Dr. Bettmann and himself the figures, which dated back seven years, represented largely the posterior operation. This operation, with the Finney operation, included all but 8 per cent. of the total number. In a general way, therefore, these statistics represented the modern type of operation. As to the duration of the symptoms, almost the entire number of these patients were chronic cases. In only four of them was the illness four months or less in duration, and in the bulk the history dated back from two to fifteen years. They were cases that were not likely to change much without operation. In 93 per cent. the indications for operation were clear, pointing to pyloric obstruction, chronic ulcer, or cancer. In only 7 per cent. was the operation done for symptoms alone, without any lesion being found at operation. The immediate mortality was 10 per cent. In part, at least, this high mortality must be due to the fact that quite a number of the cases, certainly in the East, were hospital patients, people in poor circumstances and in poor condition at the time of operation. The worst results were reported in the class of neurotic cases in which no lesion whatever was found; only 40 per cent. of these improved, and it was a question whether the improvement was due to the operation. This was the type of case which the surgeon would probably let alone in the future.

Dr. Arpad G. Gerster of New York City said the high mortality after gastroenterostomy which had been shown in these statistics did not necessarily depend upon the operation itself. There were extraneous fac-

tors that influenced the final result, and one of extreme importance was the dietary treatment of these patients after operation. If the surgeon who performed the operation did not supervise the diet of his patient for ten days or a fortnight afterwards, he would be very apt to see disturbances occur that would lead to hemorrhage and other complications. The very early application of the stomach tube after gastroenterostomy or other plastic operation was sometimes extremely beneficial to the patient, in spite of the contrary view generally prevailing among medical men. In many instances leakage and hemorrhage following operation were the result of permitting large quantities of slime and blood and liquid to collect in the stomach.

Dr. S. J. Meltzer of New York City, discussing the newer methods for the earlier recognition of cancer, referred to that devised by Dr. Charles A. Elsberg of New York, which consisted essentially of injecting washed human blood corpuscles subcutaneously into a patient who was supposed to have cancer. Within six hours a characteristic local reaction occurred. The underlying idea was that the serum of the cancer patient hemolyzed the red blood cells of the normal human being.

Dr. Henry L. Elsner of Syracuse, speaking of cancer of the stomach, said that these patients, unfortunately, did not, as a rule, present themselves early to the physician; hence, they did not come early enough to the surgeon. This was the case with Mikulicz himself—a man who had given his life's energy to this very subject. He had cancer of the stomach, and when he presented himself for operation the condition was so far advanced that it was impossible to relieve him. If a man, after 50, who had never before had any symptoms referable to the stomach began to complain of digestive troubles, one should be suspicious of carcinoma. The speaker said that in his clinical work he had not met with many cases of ulcer of the stomach that were followed subsequently by the development of carcinoma.

Dr. William J. Mayo of Rochester, Minn., said that surgeons started out with the idea that chronic indurated ulcer of the stomach was surgically curable, and the question naturally arose, why should ulcer patients wait so many years to develop obstructive lesions? Why could we not relieve them surgically at an earlier period? Clinical observation, notoriously unreliable, was responsible for the commonly accepted views concerning ulcer. These were: (1) That the ulcer was in the stomach in 90 per cent. of cases; (2) that it was a disease of women; (3) that ulcer did not necessarily show on the peritoneal surface of the organ involved, and therefore the fact that the site of the ulcer could not be located did not eradicate the theory that it was present. Based on this unreliable information, surgeons began to operate on women who had clinical symptoms which were thought were due to ulcer, and who had the text-book symptomatology. Naturally, a number of patients were operated on unnecessarily.

Dr. John A. Lichty of Pittsburg said he had had some thirty gastroenterostomies without a single death, so that the immediate mortality of 10 per cent. given by Drs. Bettmann and White after the operation for benign conditions did not refer to his cases. In one of his malignant cases the patient died of cerebral embolism within four weeks after the operation. He believed that the fault of the high mortality figures quoted by some of the speakers rested with the surgeons. Only competent men should be selected to do these operations. Referring to the lateness of the development of cancer in some instances, Dr. Lichty said that one of his cases died four and another five years after gastroenterostomy. In both of these there was malignant disease, and in both of them, at the time of operation, they were fairly certain that they were dealing with malignant disease, but the condition of the patient did not warrant them in taking the chances of doing a resection of the pylorus.

Dr. A. J. Ochsner of Chicago said we should look upon the entire apparatus as a digestive machine, and try to get it back into its normal condition, if possible, without operation. If that could not be done, then we should overcome the obstruction and the causes of the irritation by gastroenterostomy. The opening should always be made at the lowest point, and should be sufficiently large. By doing this we had a machine less perfect than the original, but better than it was in its impaired condition.

Mr. W. Arbuthnot Lane of London, Eng., said the location of the ulcer of the stomach or duodenum was usually at the points of greatest strain, namely, on either side of the acquired attachment of the pylorus and first section of the duodenum, and between that attachment and that of the esophagus. The associated autointoxication resulting from intestinal stasis in all probability rendered the mucous membrane more liable to undergo ulceration. The difference in the form of the abdomen in the two sexes, and the probable consequent variation in the character of the acquired fixation of the pylorus, were responsible for the varying frequency of the locality of the ulceration in the male and the female.

Dr. John P. Sawyer of Cleveland said we should recognize the value of gastroenterostomy when the indications for it arose. He tried to induce his patients to have it done early, and it ought to be done safely. As to the question of cancer of the stomach and the "precancerous" stage, the speaker said he had seen several cases where the cancer was indubitably grown on the base of an ulcer, but he had seen a great many more which did not appear to have any relation to previous ulcer. It was not to the point, however, whether this or that particular case developed from an ulcer or not. The fact remained that a considerable number of cases of ulcer of the stomach did develop into cancerous growths, and this emphasized the importance of thoroughly treating every case of ulcer in order to prevent, if possible, the development of cancer at a subsequent period.

The discussion was continued by Dr. Ludwig Kast of New York and was then closed by the readers of the papers, Drs. Cannon, Murphy, Bettmann, and Finney.

Tuesday, June 8—Second Day.

Gastric Symptoms and Gallstone Disease.—Dr. Harry Adler of Baltimore read this paper. (See page 599.)

Dr. H. W. Bettmann of Cincinnati said it was hard for him to see any connection between bile absorption and ordinary attacks of pain originating in the gall-bladder. He did not see why there should be any absorption under those conditions, and even if there was absorption of bile it did not necessarily point to gall-bladder trouble. In regard to the difficulty Dr. Adler mentioned in studying the relationship of gastric symptoms to obscure or undiscoverable gall-bladder disease, the speaker said he believed that as we became more experienced we would take it as a pretty good guiding principle that when the stomach analysis and examination did not reveal gastric conditions which accounted for the symptoms of the patient we should look outside of the stomach for the seat of the disease.

Dr. JOHN A. LICHTY of Pittsburg, referring to the bile test spoken of by Dr. Adler, said the presence of bile in the urine might not necessarily be indicative of gall-bladder trouble. We could only say that the presence of bile in the urine was significant of something, and it was for us to learn its true meaning and search for the source of the trouble.

Dr. D. D. ROBERTS of Brooklyn said he thought the time was coming when gastroenterology would be on a far better basis through giving up a great many of our ideas regarding functional disturbances of the stomach. His experience had led him to believe that many of these so-called functional disturbances had a deeper underlying cause if we could but find it. This might lie in the gall-bladder or in the appendix, or in an ulcer of the stomach or duodenum, or perhaps the lesion was in the large intestine.

Dr. JOHN P. SAWYER of Cleveland, discussing the Rosin test, said he had for many years resorted to it as a routine measure, and with it he had found bile in the urine in such a surprisingly large proportion of cases that he could not believe it indicated the presence of gallstones in every instance. He had frequently found it in patients who had no symptoms or suggestion of gallstone disease. He believed it had some significance, and when found it should lead us to question the patient carefully for symptoms of cholelithiasis, but he had also found it in cases of catarrhal gastritis, pure and simple, which cleared up under treatment.

The discussion was closed by Dr. Adler.

Foreign Body Associated with Carcinoma of the Pylorus.—Dr. I. HARRIS LEVY of Syracuse showed this specimen, which had been found at operation. It consisted of a large mass of vegetable fiber, which had either taken root and grown in the stomach, or else it was some vegetable that the patient had eaten at some previous time and which, owing to the obstruction, had been forced back against the fundus. The speaker said he was inclined to the latter explanation.

Demonstration of a Corset for Visceroptosis.—By Dr. CHARLES D. AARON of Detroit.

AMERICAN DERMATOLOGICAL ASSOCIATION.

Thirty-third Annual Meeting, Held at Philadelphia, Pa., June 3, 4 and 5, 1909.

(Special Report to the MEDICAL RECORD.)

THE PRESIDENT, DR. THOMAS CASPAR GILCRIST OF BALTIMORE, IN THE CHAIR.

First Day—Thursday, June 3.

President's Address.—Dr. T. CASPAR GILCRIST of Baltimore, in his opening address, referred briefly to some of the more recent advances in dermatology. He mentioned first the striking advance which had been made in the etiology of syphilis in the serum deviation test of Wassermann and Noguchi, and in the dark-field illumination for the detection of the spirochæta pallida. Since Schaudinn's discovery of its origin, only about three years ago, confirmatory evidence had accumulated to such an extent that the spirochæta pallida was now accepted by practically all authorities as the cause of syphilis. Neisser's wonderful work on the investigation of syphilis in apes ranked with Schaudinn's discovery. The speaker also referred to the value of the von Pirquet test in cutaneous tuberculosis, especially in children, which had proven to be reliable and had received confirmation from a number of sources. He regarded the use of the acne vaccine as a valuable addition in our treatment of acne vulgaris, and stated that the etiological relationship between the *Bacillus acnes* and acne vulgaris was now being confirmed by various investigators. The fact that the bacillus was usually present in large numbers in the skin did not weaken its causal relationship to acne; like the tubercle bacillus and many other microorganisms which were normally present in the human body, the *Staphylococcus albus* was normally present in the skin and only became pathognomonic when the occasion arose. In closing his remarks Dr. Gilcrist said that the epidemic of pellagra in some of the Southern States should receive more attention from the dermatologists in that section of the country, as it offered such a good field for investigation into the etiology of the disease.

A Tumor of the Hypophysis (Pituitary Body) Associated with Adipositas Cerebralis.—By Dr. GEORGE PERNET of London, Eng.

The Psychological Aspect of Feigned Eruptions.—Dr. PERNET said that for many years he had been interested in feigned eruptions under the various names by which they had been known, and he thought that the dermatologist had rather neglected the psychological aspect of these cases. In many of them he believed that we were dealing with an altered personality, and that that was the correct attitude in which to regard them.

Notes on the Treatment of Alopecia Areata and Dermatitis Exfoliativa.—Dr. GEORGE T. JACKSON of New York said that during the past four or five years he had treated eight cases of alopecia areata with the Piffard iron spark lamp, and a study of these cases had convinced him that the use of this lamp was of decided benefit in the treatment of this affection. Even in long-continued general alopecia it had brought the hair in, although not permanently. In all the usual cases recovery had taken place. The hair, when it returned, was of normal color and texture. The only objection to the treatment was that it required the expenditure of a good deal of time. Dr. Jackson also reported a number of cases of dermatitis exfoliativa in which the eruption was favorably influenced by large doses of quinine.

Lymphangioma Xanthelasmoideum.—Dr. WILLIAM S. GOTTHEIL of New York read a paper on this condition, which he described as a capillary lymphangioma, with colloid degeneration of the elastic tissue. It appeared in the form of faint yellowish or brownish-white plaques, of very slow growth, so slightly raised above the general surface as to be impalpable as a tumor, and of a soft, velvety consistence. Each plaque was composed of a multitude of closely aggregated angular lesions. There were no vesicles and no fluid was obtainable by puncture. The microscope showed dilatation and minute cyst formation of the most superficial and subpapillary lymphatics, with degenerative changes in the elastic tissue. There were no other abnormalities; no fat and no xanthoma cells. The clinical appearance resembled some forms of xanthoma planum. Dr. Gottheil said the only other case he could find recorded was that by Thibierge, in the *Ikonographia Dermatologica*, Fasc. II., Tab. 15. The abnormality was probably less rare than this fact would seem to indicate.

Erythroderma Squamosum (Parapsoriasis).—Dr. A. RAVOGLI of Cincinnati said that this affection, which had been known only recently and was of rare occurrence, was a variety of *erythrodermie pityriasique en plaques*, consisting of patches formed by licheniform papules aggregated and covered with thick scales. The microscopical examination showed that the lesion was not very superficial, as reported in some cases, and was capable of causing atrophic spots in the site of the primary lesion; the disease was chronic, improvement being followed by relapses. Thus far the remedies internally given and externally applied had produced very unsatisfactory results. Injections of a 10 per cent. solution of cacodylic acid were the only means with which he succeeded in producing a visible improvement in the eruption. In conclusion, Dr.

Ravogli said that after studying this obscure disease in its hybridity we could not refuse entirely the opinion of Civatte that tuberculosis might have some influence in the production of the eruption, and that with successive studies and more observations the disease might finally be ranged among the tuberculides.

Some Observations on the Results of the Wassermann Test in Scleroderma.—Dr. Henry H. Whitehouse of New York in this paper reported five cases of diffuse scleroderma. Three of these gave a strongly positive Wassermann reaction, one was faintly positive, and one was negative. The two latter, however, had been under antisyphilitic treatment, the first for over a year, and the second for six months, a sufficient length of time in each instance to negative the test had both been cases of undoubted syphilis. In two cases of the band-like morphea type the reaction was negative in both instances. These seven Wassermann tests were made by three different investigators, and in each instance the original Wassermann and the Noguchi modification was done, in some instances more than once, and in all with numerous control experiments. Dr. Whitehouse said that while the facts here presented could be little more than suggestive, the possible results of further observations along this line might well excite our interest. If, as most believed, the vascular changes were primarily the seat of the trouble in scleroderma, it was not improbable, in view of the histological similarity of these changes to those in syphilis, that, should the Wassermann observations here recorded be later confirmed, syphilis might be found to be an etiological factor in this disease.

Result of the von Pirquet and Wassermann Tests in Twenty-nine Orthopedic Cases (Osteopathies of Quarternary Syphilis, Gaucher).—By Dr. James M. Winfield of Brooklyn. In age, these patients ranged from six months to fourteen years. Ten were suffering from Pott's disease; in eleven the hip joint was involved; three had disease of both hip and spine; two had suppurating sinuses of the ankles, and two had disease and sinuses of the wrist and fingers. Ten of the twenty-nine presented somatic evidence of inherited syphilis, while sixteen had no bony malformations suggestive of hereditary lues. All of the twenty-nine were tested for tuberculosis by the von Pirquet method, and in all, excepting one, the result was positive; some, however, reacted more positively than others. The Wassermann and Noguchi tests were made at different times and at long enough intervals between to prevent either from modifying the other. Four of the cases that showed syphilitic stigmata were positive to the Wassermann test; six who did not show any such evidence were also positive. Those that were most markedly positive were the cases that had two or more dystrophies. Since all of the cases reacted to the von Pirquet test, it was strong presumptive evidence that all were suffering from tuberculosis, and if the Wassermann test was to be relied upon it brought up the question, was it possible for tuberculosis and syphilis to exist simultaneously in the same individual, and could you always get a positive Wassermann reaction in all cases of inherited syphilis, provided, of course, that the child had received no mercurial treatment? From a study of these cases it was safe to conclude that syphilis was an important factor in many of the suppurating osteitides of childhood. Perhaps it would be questionable to assume that all cases of suppurating bone disease in childhood that had the somatic evidence of syphilis and were positive to the Wassermann test were examples of quarternary syphilis; but one would be justified in assuming that in many cases the underlying etiological factor was syphilis, and that the inherited taint had rendered the resistance of the individual so low that he became an easy victim of tuberculosis.

Dr. Howard Fox of New York said that so far as he knew Dr. Winfield's paper was the first one relating solely to the Wassermann test in orthopedic cases. He congratulated the author on having taken up this line of work, which might lead to valuable results.

A Comparison of the Wassermann and Noguchi Complement-Fixation Tests.—By Dr. Howard Fox of New York.

Exhibition of Dermatoses by Lumière Plates—Stereopticon.—By Dr. Howard Morrow of San Francisco and Dr. M. B. Hartzell of Philadelphia.

Second Day—Friday, June 4.

Meralgia Paresthetica.—Dr. Samuel Sherwell of Brooklyn gave a brief report of a typical case of meralgia paresthetica, occurring in the person of the author. For about the past ten years, in the outer and lower two-thirds of the left thigh, after strenuous and long-continued exertion, as of walking, riding, or cycling, there occurred in the region supplied by the external femoral cutaneous nerve the following symptoms: The region became the seat of a variety of perverted sensations, as of tingling, tenseness, or still more acute superficial tearing and darting pain, with numbing of sensation just above the patella. The rest of the limb or its cutaneous envelope was unaffected and entirely normal, and the symptoms enumerated soon subsided on resting, but could be brought on readily by resumption of exertion. The painful sensations were like nothing so much as those of zoster, and in the writer's belief they were caused by the same mechanical means, namely, pressure on the nerve in its continuity, although probably not from the exudative pressure which occurred in zoster. No objective phenomena accompanied the attacks. As regarded treatment, rest and perhaps slight massage brought on rapid though, unfortunately, only temporary relief.

The Etiology of Psoriasis.—Dr. Sigmund Pollitzer of New York opened a general discussion on this subject. He reviewed at length the various hypotheses that had been advanced concerning the nature of psoriasis, and said that our knowledge of the subject at the present time might be summed up in the following conclusions: 1. That rheumatism, gout, neuroses, and heredity were not direct etiological factors in the production of psoriasis, but in the present state of our knowledge it could be neither denied nor affirmed that they might have some bearing on the obscure conditions of the system which rendered it more or less susceptible to infection. 2. That psoriasis was one member of a group of parakeratoses to which seborrhea corporis, and (in part) eczema seborrheicum belonged. 3. That it was most probably due to an external microbic infectious agent.

Parasitism of Psoriasis.—Dr. Jay Frank Schamberg of Philadelphia, in discussing this subject, said that three propositions might be formulated for consideration: 1. That psoriasis might be the result of the circulation in the fluids of the body and deposition in the skin of a microparasite, analogous to what was observed in syphilis and variola. 2. Psoriasis might be due to the implantation upon the skin of an exogenous parasite, as was observed in ringworm, favus, and tinea versicolor. 3. The disease might be due to one of the common facultative parasitic organisms ever present upon the skin in individuals in whom a constitutional predisposition rendered the soil favorable. After discussing each of these propositions in detail, and reviewing the literature and experimental work that had been done on the subject, Dr. Schamberg said it might be argued that the failure to autoinoculate psoriasis in the vast majority of subjects operated against the assumption that it was a local parasitic disease due to exogenous organisms. It might, furthermore, be argued that if the lesions of psoriasis were due to the implantation of a parasite upon the skin of a susceptible individual,

inoculation with lymph, blood, and scales from a diseased patch upon the healthy skin in the same patient might be reasonably expected to reproduce psoriasis lesions. Our lack of knowledge, however, concerning possible conditions of immunity in this connection made it unwarranted to deduce any positive conclusions of the character indicated. The inability to autoinoculate psoriasis patients would not at all affect the hypothesis that psoriasis was a constitutional, infectious disease. From what had been stated it was obvious that no definite conclusion as to the parasitism of psoriasis was warranted. The mode of growth and configuration of the patches, the occasional instances of apparent communication of the disease, and the Destot inoculation were arguments in favor of parasitism which could not be decisively brushed aside. On the other hand, the general behavior of the disease, the common experience of observers as to the absence of contagion, and the almost uniform failure of inoculation experiments constituted strong evidence against parasitism. Wisdom should prompt us, in the light of our present knowledge—or, more accurately speaking, in the dimness of our inadequate knowledge—to commit ourselves neither to positive affirmation nor to uncompromising negation.

Dr. James C. White said that psoriasis might be called a family disease, or, to a certain extent, a hereditary disease. We knew that it succeeded quite a number of other cutaneous diseases, but that did not necessarily imply any etiological relationship between the two. When we mentioned these two factors as having some direct influence on the production of psoriasis he thought we had told the whole story, so far as we had any direct knowledge of the nature of this disease.

Dr. Louis A. Duhring of Philadelphia said that up to the present time we had no convincing proof of the parasitic origin of psoriasis.

Dr. L. Duncan Bulkley of New York said that all were ready to acknowledge that there was something back of psoriasis that we did not know anything about. There was no question that there was something on the skin which produced these lesions on a favorable soil. He had some patients under his care for many years in whom recurrent attacks of psoriasis were clearly traceable to errors in diet, resulting in faulty metabolism.

Dr. James Nevins Hyde of Chicago said that in collecting statistics of the disease in this country the figures from one part of the country must be dissociated from those of other parts. For example, in the Northwest, where he lived, the percentage of these cases greatly exceeded that in the South. He referred to the relative infrequency of the disease in the negro, and to the fact that it never appeared in the lower animals, which shared most of the parasitic diseases with the human family.

Dr. E. B. Bronson of New York spoke of the relative importance of the local causes from parasitism, and the causes which existed in the constitution of the skin. He thought there was no question that psoriasis was a dermatological disease, due to a local parasite. There was no more reason for regarding it as a constitutional disease because it was influenced by gout or rheumatism or improper diet than it would be to regard acne as a constitutional disease. The parasites that produced it were probably omnipresent, but in addition to these we had to have a receptivity of the skin.

Dr. Henry W. Stelwagon of Philadelphia said the consensus of opinion was that the lesions of psoriasis were due to a parasite, but that underlying that we had a peculiar susceptibility of the skin or of the general system, and that the latter could be evoked by various causes, such as shock, faulty metabolism, etc.

Dr. Douglass W. Montgomery of San Francisco said he was decidedly skeptical in regard to the parasitology of psoriasis or eczema. As far as the appearance of the lesions of psoriasis after scratching was concerned, we could get the same effect in urticaria and lichen.

Dr. Samuel Sherwell of Brooklyn said that during his forty years of practice he had seen many thousands of cases of psoriasis, and he had never seen but one case, so far as his memory carried him back, that was associated with tuberculosis, and in that instance the tuberculosis was of a fibroid character and the patient lived for a long time. That spoke in favor of the general good health of the psoriatic patient. In regard to the treatment of psoriasis, he could corroborate what had been said as to the efficacy of a change of climate or the beneficial effects of a sea voyage, and he recalled one case where a woman who was sent to London for treatment recovered before she arrived there.

Dr. Hermann G. Klotz of New York referred to the tendency of many cases to get well, or almost well, spontaneously during certain seasons of the year. In some the eruption broke out in the summer; in others in the winter. He believed that this phase of the disease could easily be reconciled with the parasitic theory.

Dr. George Pernet of London, Eng., said he had many times observed that psoriasis cases exhibited a primary patch—perhaps two—which remained for some weeks or months before there was any generalization of the disease. Such an extension of the eruption was in favor of the parasitic theory. With regard to the effects of diet in psoriasis, Dr. Pernet said he had not been able to satisfy himself that it played the slightest rôle in the evolution or development of the affection, excepting, perhaps, the use of coffee or alcohol in acute or subacute cases.

Dr. M. B. Hartzell of Philadelphia said he had never been able to convince himself that a meat or vegetable diet had anything whatever to do with the affection. The one theory that appealed to him was the parasitic view.

Dr. James C. Johnston of New York, discussing the parasitic theory of psoriasis, with which the speaker was in considerable sympathy, said the controls to prove it had to be numerous—in fact, almost wasteful. The experiments must be done on the individual himself and on members of his family, both on those that seemed predisposed and upon completely healthy individuals, as well as on laboratory animals.

Dr. Thomas C. Gilcrist of Baltimore said the work to prove or disprove the parasitic origin of psoriasis must be carried along experimental lines, and would doubtless be greatly aided by Schaudinn's introduction of the dark-field illumination, which might make it possible to find the parasite.

The discussion was then closed by Drs. Pollitzer and Schamberg.

Further Observations Upon the Elastic Tissue in Epidermolysis Bullosa.—By Dr. Martin F. Engman and William H. Mook of St. Louis. In 1906 the authors reported the histological study of two cases of epidermolysis bullosa, in which they found the elastic tissue absent in the upper part of the derma, both in the region of the bulla and in the normal skin. One case was more marked than the other. They now wished to submit the histological study of the normal skin of two additional cases of the same disease, in which they found sufficient evidence to strengthen the assumption that the disease was due to congenital deficiency, or absence of the elastic tissue in the derma.

The Elastic Tissue of the Skin.—Dr. Charles J. White of Boston read a paper on this subject, which was discussed by Drs. Engman, Schamberg and Pusey.

Notes on Certain Diseases of the Skin Observed in the Far East.—By Dr. L. Duncan Bulkley of New York. This paper gave the result of the writer's observations during recent extended travels in the far East, and included studies of cases of leprosy, syphilis, frambœsia,

epithelioma, cancer, Madura foot, tinea imbricata, tinea favosa, acne, eczema, etc. Dr. Bulkley said the first thing which struck him everywhere was what seemed to him the relative infrequency of diseases of the skin throughout the East. Although he visited very many hospitals in outpatient clinics in Japan, Korea, China, the Philippine Islands, Siam, Ceylon, India, and Egypt, and made constant inquiry and search for them and saw hundreds of patients, there were relatively few with dermatological troubles, and this in spite of the fact that one was constantly told that in all Eastern countries diseases of the skin were very prevalent. He could hardly explain this contradiction, except that as affections of this class were pretty troublesome and rebellious, and were relatively little known or studied by the general physician, such cases as did occur made more of an impression and gave rise to the idea that diseases of the skin were especially frequent. There were, however, many cases of vegetable parasitic disease of the skin seen everywhere, to which no attention seemed to be paid.

Treatment of Some Chronic Inflammatory Diseases of the Skin.—By Dr. Louis A. Duhring of Philadelphia. In this paper the author said it was his purpose to deal with certain underlying principles, rather than with details pertaining to drugs and formulæ. Important and valuable as the latter might prove in suitable cases, yet of much greater importance was an understanding, where that was possible, of the general and specific etiological factors that occasioned the cutaneous lesions. It pertained to the manifold causes which were actually the *fons et origo* of the cutaneous lesions of many diseases of an inflammatory nature, especially those characterized by chronicity, rebelliousness to local treatment and a tendency to persist and recur. Thus, eczema and psoriasis afforded instances that illustrated the fact that the methods of therapy commonly employed for their amelioration or cure were often wholly ineffectual. It might be pertinently asked why it was that some cases of eczema, psoriasis, or acne were readily amenable to treatment, local or internal, or both, while others did not respond to the same line of treatment. The reason might be found in the fact, not sufficiently recognized, that while the cutaneous manifestations might be the same, or closely similar in many cases, the causes producing them were varied and different, and it was the latter that, if possible, we should detect, treat, and remove. For nearly all, if not all, of the chronic persistent or recurrent cases of eczema, psoriasis, and other diseases, there existed internal etiological factors, specific or general, that must be found and relieved if the patient was to be permanently cured of the cutaneous disease. Most of the authors of works on skin diseases did not lay sufficient stress upon this phase of the subject. Dr. Duhring said that each year he was more and more impressed with the importance of this principle and its practical application; more and more did he recognize the intimate relation in many cases of the diseases under discussion to the general economy; in short, of the relation of such cutaneous diseases to general medicine. It naturally followed that only by treating such internal conditions, whatever they may be, could such cases be satisfactorily and successfully and permanently relieved of the cutaneous disease.

Cases of Bromide Eruption Mistaken for Blastomycosis.—By Dr. Oliver S. Ormsby of Chicago. The paper embraced a clinical description of three cases, the patients' ages, respectively, being seven, sixteen, and twenty-nine years. The lesions in each case were practically situated in the same region of cutaneous surface and closely resembled each other, the group being almost wholly indistinguishable from blastomycosis. Each of these three patients was the subject of epilepsy, and had been given bromide. Blastomycosis was ruled out, etiologically, in each case. From the foregoing it appeared to be essential in any case suspected to be one of blastomycosis in which bromides had been exhibited to positively demonstrate the presence or absence of the causative organisms (blastomycetes) before drawing final conclusions.

Preliminary Report Upon a Case of Multiple Benign Cystic Epithelioma and Multiple Fibroma in the Same Patient.—By Dr. E. Wood Ruggles of Syracuse. The case presented several variations from those previously described. In the first place, multiple epithelioma in this location was infrequent, and had never been found associated with multiple fibroma. The disease developed at the age of six or seven years, which was at a much earlier period of life than any other case, excepting Jacquet's, which developed at eight years. There were no central depressions, telangiectasia, or milia upon any of the lesions, nor were any of the dark bodies described by Phillippson and Brooke present. Marked improvement in the appearance of the lesion had occurred under application of carbonic acid snow, the effect upon the larger and also upon the smaller contiguous lesions having been most striking. In connection with this case, Dr. Ruggles demonstrated an improved applicator for the use of carbonic acid snow.

A Case of Pemphigus Vegetans, with Special Reference to the Cellular Elements Found in the Lesions.—By Dr. M. B. Hartzell of Philadelphia. The paper embraced the clinical history of a case of pemphigus vegetans that had recently come under the author's observation and a histopathological study of the lesions. The speaker said his attention was especially directed to the bullous lesions chiefly because these presented features which, while not altogether new, were extremely interesting and somewhat different, at least in degree, from those commonly described as belonging to this variety of pemphigus. The great number of eosinophiles found in the blebs, in the papillæ, and in the subpapillary part of the corium was so extraordinary that this feature seemed to him especially deserving of atttention.

The Increase of Certain Contagious Diseases Following the Great Fire in San Francisco.—By Dr. Douglass W. Montgomery and Dr. Howard Morrow of San Francisco. In this paper the authors limited themselves to the consideration of impetigo contagiosa, typhoid fever, and plague, because the behavior of these infections, following the great fire, showed some very interesting points in the etiology and correlations of all three. Until recently they looked upon impetigo contagiosa as being preeminently a disease of childhood and a contact disease, and if a case was seen in an adult it was regarded as exceptional. A study of the cases seen between May, 1906, to the end of June, 1908, showed that instead of there being more children than adolescents and adults affected, there were ninety-five adolescents and adults and only twenty-seven children. These figures showed that there were three and one-half as many infections in the balance of life as in childhood. In connection with these cases two striking facts were noted: that the increase of infection occurred among the members of the class that frequented barber shops, namely, the adult males. The increase in impetigo was found to be coincident with the increase in typhoid fever, and practically coincident also with the development and increase in plague. From April, 1906, the time of the fire, to the end of December, 1906, a space of eight months, 1,215 cases of typhoid fever were reported, and because of the disturbed conditions many were unreported. During the following six months less than 200 cases developed, although inspection was much more strict. During all this time frequent examinations were made of the city water and milk supplies, always with negative results, so that the city authorities were forced to the conclusion that the spread of this disease was by flies in the same manner as shown by Reed.

Vaughan, and Shakepeare in their able investigations in the military camps during the Spanish War. The first reported case of plague after the fire appeared in May, 1907, and up to February, 1908, 160 cases were observed. Since that date no case of plague had been found. Such a surprising good result was accomplished by a series of measures taken by the Marine Hospital Service. The rat was the point of attack, as he and his accompanying flea were the bearers of plague. Inspection was severe and in accordance with the will of the people. Buildings were rat-proofed with concrete floors, and poison and traps were used in the sewers. Typhoid fever and impetigo fell away instantly almost to nothing, and plague was wiped out. In conclusion, the authors stated that, while impetigo contagiosa must be a filth disease, in many instances it was a fly-borne disease and not altogether a contact disease.

Granuloma Annulare, with Report of Case.—Dr. Grover W. Wende of Buffalo reported this case. The patient was a man, forty-nine years old, whose skin eruption dated back about two years, and had a deep-seated node upon the nape of the neck as its initial lesion. It was in the form of a flat, red-white nodule, without itching or burning. Other similar lesions appeared, and in two or three months they had extended to the hair-line back of the ears and to the front of the neck. The inception of some of the lesions was abrupt, somewhat resembling urticaria. Some nodes would disappear without change; others assumed figure formations. The eruption gradually extended to the cervical region and the upper chest and hands. Clinically and histologically, the case bore a striking similarity to those reported by Dr. E. Graham Little as granuloma annulare (*British Journal of Dermatology*, July, 1908, p. 213). Dr. Little had examined a photograph of Dr. Wende's case, and expressed the opinion that it might be one of granuloma annulare, although the multiplicity of the lesions was opposed to that diagnosis. Nevertheless, he had seen a case showing as many.

The last day's session of the association was devoted to the exhibition of patients and the demonstration of microscopical sections.

STATE BOARD EXAMINATION QUESTIONS.

Vermont State Board of Medical Registration.

July, 1909.

ANATOMY.

1. Describe the bony pelvis, and state what bounds the cavity of the true pelvis above.
2. Give the anatomy of the hip-joint.
3. Give origin, insertion, nerve supply, and action of the pronator radii teres muscle.
4. Describe the circle of Willis.
5. Describe the peritoneum and its reflections.
6. Bound the axillary space, and name its contents.
7. Describe and bound the fourth ventricle.
8. Describe the prostate gland and give its relations.
9. Describe the male urethra.
10. Name the coverings of femoral hernia.

BACTERIOLOGY.

1. Classify bacteria, and name the two most common pyogenic bacteria.
2. Differentiate the gonococcus from other diplococci.
3. By what culture characteristics may the colon bacillus be distinguished from the typhoid bacillus?
4. Describe the bacillus of Eberth, and give Widal's test for typhoid fever.
5. What bacteria are liable to be mistaken for the tubercle bacillus, and how may this error be avoided?

PHYSIOLOGY.

1. Describe ciliated epithelium and (*a*) state where it is found most abundant; (*b*) what is the function of ciliated epithelium?
2. Name some of the bodily states which lessen the alkalinity of the blood.
3. What is the office of the columnæ carneæ?
4. What post-mortem tests should be applied to prove that air has entered the lungs of a supposedly stillborn child?
5. Describe (*a*) the functions, and (*b*) secretions of the stomach.
6. What is the function in digestion of (*a*) saliva, (*b*) bile?
7. How do the products of digestion find their way into the blood?
8. What is the cerebrospinal system of nerves, and to what parts of the body are its fibers chiefly distributed?
9. State where in the human economy the following substances are found: fibrin, mucin, chondrin, leucin, hippuric acid.
10. Name the structures in the body whose functions are doubtful or unknown.

HYGIENE.

1. Into what general classes are foods divided? Give examples of each.
2. Describe the physiological action of alcohol.
3. What hygienic precautions should be observed by a pregnant woman?
4. If a chemical analysis of water revealed the presence of nitrates and nitrites (*a*) would this condemn it for drinking purposes? (*b*) If so, why?
5. Describe the preparation of patient, surgeon, instruments, and surroundings for operative procedures.

MATERIA MEDICA AND THERAPEUTICS.

1. State properties, action, and preparations of tannic acid.
2. Name four spinal stimulants and state the action of such drugs.
3. Write a prescription for asthma, Basedow's disease, infantile bronchitis.
4. How would you proceed if called to see a child (one year) in convulsions?
5. Name three hypnotics, state action of each, and when indicated.
6. Name varieties of expectorants, name three drugs under each, and give dose of same.
7. How would you manage a case of (*a*) Lobar pneumonia in an adult? (*b*) Catarrhal pneumonia in a child (six months)?
8. How would you manage a case of diabetes mellitus?
9. Give your treatment, prophylactic and medicinal, for a dilated heart.
10. Name three preparations of the following and state incompatibles and indications for same: hydrastis, cinchona, creosote, bromides.
11. Outline the general principles of treatment in a case of poisoning.

CHEMISTRY.

Answer any five questions.

1. (*a*) State the physical and chemical properties of O. (*b*) Mention four methods by which O may be obtained.
2. (*a*) How many oxides of N are known? Which forms acid? (*b*) State composition properties and test for carbonic acid.
3. (*a*) What elements does magnesium resemble? (*b*) Complete $MgCO_3 + H_2SO_4$.
4. (*a*) What are alums and state four important ones. (*b*) Describe and give diagnostic importance of Ehrlich's diazo-reaction.
5. (*a*) State characteristics of the arsenic group of metals. (*b*) Show by equations the formation of dibasic acids from monobasic acid, from alcohol.
6. How is urea formed in the body.
7. What is acholia? What is cystin?

PATHOLOGY.

1. (*a*) What are the causes of fever? (*b*) What are the effects of fever?
2. (*a*) Mention all the pathological conditions which may produce hemoptysis. (*b*) The same of hematemesis.
3. Give the pathology of tubercle.
4. Explain the propagation of tapeworm.
5. Mention the different varieties of goiter and give their pathological differences.

PRACTICE OF MEDICINE.

1. How would you diagnose typhoid fever?
2. Give differential diagnosis between smallpox and chickenpox.

3. Discuss the treatment of pulmonary tuberculosis among the poor.
4. Give treatment for the different pleural effusions.
5. Give treatment for the two commonest of the valvular heart lesions.
6. Discuss prognoses in cerebral embolism and cerebral hemorrhage.
7. Write a short article on epilepsy.
8. Discuss intestinal neuroses.
9. How would you manage a case of nervous prostration in a very poor family.
10. What are the comparative urinary findings in the first stages of chronic parenchymatous and chronic interstitial nephritis.

OBSTETRICS.

1. Describe the changes which occur in the external genitals during pregnancy.
2. Give presumptive signs of pregnancy. Give positive signs. How early during pregnancy would you expect to be able to make a positive diagnosis?
3. Give symptoms and treatment of albuminuria of pregnancy.
4. Describe in detail the preparation of the patient pending labor.
5. How would you resuscitate a child apparently stillborn?
6. Give diagnosis and management of a case of occipito-posterior presentation.
7. In a tedious but otherwise normal labor, what are the symptoms which would lead you to interfere? What would you do?
8. Describe the varieties of placenta prævia. To what dangers does the condition expose the mother and child? How would you manage a case?
9. Give symptoms of impending eclampsia. How would you treat a case? What would be your treatment should convulsions ensue?
10. Name the more common pathogenic bacteria that may infect a woman during the puerperium. To what conditions may such infection give rise?

GYNECOLOGY.

1. Give symptoms of imperforate hymen. How would you manage a case of long-retained discharges due to such conditions?
2. Differentiate simple catarrh from gonorrheal vaginitis.
3. Define rectocele, cystocele, enterocele.
4. Give etiology, symptoms, and treatment of chronic ovaritis.
5. What are the causes of uterine displacements? Which one is of the greatest interest from the obstetrician's standpoint?

SURGERY.

1. Name the different tumors of the breast, and describe Halstead's operation for the removal of carcinoma of the breast.
2. Diagnose fistula in ano and describe operation for its cure.
3. Give the symptoms of strangulated inguinal hernia. What is taxis? How long should it be continued and how soon abandoned? Describe Bassini's operation for the radical cure of inguinal hernia.
4. Give the etiology, pathology, and symptoms of empyema and describe best operation for its cure.
5. Mention the articles you would require in administering ether, the accidents likely to occur, and methods for their relief.
6. Differentiate hernia cerebri from caput succedaneum. Give treatment of the latter.
7. Diagnose fracture of the patella and describe methods of treatment.
8. Describe the various dislocations of the shoulder. Give method for reducing one variety.
9. Give the symptoms and treatment for fracture at the base of the skull.
10. Define osteomalacia and state its significance in surgery.

LEGAL MEDICINE.

1. Define the term railway spine.
2. Describe the general characteristics of gunshot wounds.
3. Differentiate paranoia and dementia paralytica.
4. What postmortem appearance would lead you to pronounce that death was due to drowning?
5. What is rigor mortis, and tell how it is produced; how long after death does it appear, and when does it disappear?

ANSWERS TO STATE BOARD EXAMINATION QUESTIONS.

VERMONT STATE BOARD OF MEDICAL REGISTRATION.

July, 1909.

ANATOMY.

2. The *hip-joint* is an enarthrodial joint, formed by the head of the femur and the acetabulum. The articular surfaces are covered with cartilage. Near the center of the head of the femur is attached the ligamentum teres. The *ligaments* are: (1) The capsular, which embraces the margin of the acetabulum above, and the neck of the femur below. (2) The ileo-femoral or Y ligament, which passes obliquely across the front of the joint, and is attached above to the anterior inferior spine of the ileum, and below to the anterior intertrochanteric line. (3) The ligamentum teres. (4) The cotyloid ligament, which deepens the acetabulum, and bridges over the cotyloid notch, being there called (5) the transverse ligament. The joint has a very extensive synoviol membrane. It is capable of the following movements: Flexion, extension, abduction, adduction, circumduction, and rotation.

3. PRONATOR RADII TERES. *Origin:* Internal condyle and supracondylar ridge of humerus, and the coronoid process of ulna. *Insertion:* Middle of outer surface of radius. *Nerve supply:* Median. *Action:* Pronation of hand, by rotating radius upon ulna; also slight flexion of forearm.

4. The *Circle of Willis* is formed: In front by the two anterior cerebral arteries (branches of the internal carotid), which are connected by the anterior communicating artery; behind, by the two posterior cerebrals (branches of the basilar artery), which are connected to the internal carotid on each side by the posterior communicating artery.

6. The axillary space is *bounded:* Anteriorly, by the clavicle, Subclavius, Pectoralis major, costocoracoid membrane, Pectoralis minor; *posteriorly,* by the Subscapularis, Teres major, and Latissimus dorsi; *internally,* by the first four ribs, first three Intercostal muscles, Serratus magnus; *externally,* by the humerus, Coracobrachialis, and Biceps.
Contents: Axillary vessels; brachial plexus of nerves, and branches; some branches of the upper intercostal nerves; lymphatic glands, fat, and loose areolar tissue.

7. The fourth ventricle is the expanded portion of the central canal of the spinal cord; it is a diamond-shaped cavity situated between the cerebellum behind, and the posterior surface of the pons and medulla in front. It is bounded: *Above,* by the valve of Vieussens and the cerebellum. *Below* by the pons and medulla. *Laterally,* by the superior peduncles of the cerebellum, restiform bodies.

8. The *prostate gland* adjoins the neck of the bladder and surrounds the beginning of the urethra, which is placed nearer the anterior than the posterior surface of the gland. It is said to resemble a horse-chestnut in shape, with the apex directed downwards. It measures about 1½ inches across its base and 1¼ inches in depth, and 1 inch from before backwards, and is held in position by the anterior true ligaments of the bladder.

The gland consists of three lobes, two lateral and one middle, and is perforated from base to apex by the urethra. The common seminal ducts open into the prostatic portion of the urethra, and are placed between the middle and lateral lobes.

Relations:

ANTERIOR OR PUBIC SURFACE.
Symphysis pubis.
Anterior ligaments of bladder.
Branches of dorsal vein of penis.

POSTERIOR SURFACE.
Rectum.

LATERALLY.
Levator ani.

BASE.
Surrounds bladder-neck.
Vesiculæ seminales.
Vasa deferentia.

APEX.
Rests on upper layer of triangular ligament.

10. The *coverings of a femoral hernia,* from without inward, are: Skin, superficial fascia, cribriform fascia, crural sheath, septum crurale, subserous areolar tissue, and peritoneum.

BACTERIOLOGY.

1. *Bacteria are classified:* (1) Cocci; (2) Bacilli; and (3) Spirilla.
Two most common pyogenic bacteria: Staphylococcus pyogenes aureus and *Streptococcus pyogenes.*

2. The gonococcus is Gram-negative, is found inside the pus cells, and will not grow on the ordinary media, but only on serum. All of these will differentiate it from other diplococci (except the meningococcus, and this latter may be differentiated by its growth on ordinary media).

3. *Cultural characteristics that differentiate the colon*

bacillus and the typhoid bacillus: (1) On gelatin plates the colonies of typhoid develop more slowly than those of colon bacillus.

(2) The colon bacillus causes fermentation with production of gas in media which contain sugar; the typhoid bacillus does not.

(3) The colon bacillus produces a strong acid reaction and coagulates milk within twenty-four to forty-eight hours; the typhoid bacillus does not coagulate milk.

(4) In peptone solution the colon bacillus produces indol; the typhoid bacillus does not.

(5) The typhoid bacillus gives the Widal reaction with typhoid serum; the colon bacillus does not.

4. *Eberth's bacillus* is a rod-shaped organism, with rounded ends, is from 2 to 4 mikrons in length, and about three-fourths of a mikron in breadth; it does not stain by Gram's method, but stains with all the anilin dyes; it has flagella, no spores, is aerobic and facultative anaërobic, and is motile.

Widal's test: Three drops of blood are taken from the well-washed aseptic finger tip or lobe of the ear, and each lies by itself on a sterile slide, passed through a flame and cooled just before use; this slide may be wrapped in cotton and transported for examination at the laboratory. Here one drop is mixed with a large drop of sterile water, to redissolve it. A drop from the summit of this is then mixed with six drops of fresh broth culture of the bacillus (not over twenty-four hours old) on a sterile slide. From this a small drop of mingled culture and blood is placed in the middle of a sterile cover-glass, and this is inverted over a sterile hollow-ground slide and examined. A positive reaction is obtained when all the bacilli present gather in one or two masses or clumps, and cease their rapid movements inside of twenty minutes.

5. *The bacteria liable to be mistaken for the tubercle bacillus* are: The bacillus of leprosy, the bacillus of the smegma, and Lustgarten's bacillus. "The differential diagnosis between these four organisms depends upon the following reactions: When stained by the carbol-fuchsin method, commonly employed in staining the tubercle bacillus, the Lustgarten's bacillus becomes almost instantly decolorized by treatment with mineral acids, particularly sulphuric acid; whereas the smegma bacillus resists such treatment for a much longer time, and the lepra and tubercle bacillus for a still longer time. On the other hand, if decolorization is practised with alcohol instead of acids, the smegma bacillus is the first to lose color. The bacillus tuberculosis and the bacillus of leprosy are both very retentive of their color, even after treatment with acids and alcohol. If, then, we treat the preparation, stained with carbol-fuchsin, with sulphuric acid, Lustgarten's bacillus becomes almost at once decolorized. If it is not immediately decolorized, heat with alcohol; if it is then decolorized, it is the smegma bacillus. If it is still not decolorized, it is either the leprosy or the tubercle bacillus."—(From Park's *Pathogenic Bacteria.*)

PHYSIOLOGY.

1. *Ciliated epithelium* generally consists of columnar epithelial cells surmounted by fine, tapering filaments or cilia; these latter move to and fro, and produce a current.

(*a*) *They are found* in the upper air passages, Fallopian tubes, ventricles of the brain, central canal of the spinal cord, vasa efferentia, and the tail of the spermotozoon.

(*b*) *Functions:* To keep foreign particles out of the respiratory tract, to assist the ovum in the Fallopian tube onwards to the uterus, to enable the spermatozoa to progress; generally—protection and motion.

2. The *alkalinity of the blood is lessened* by: Muscular exertion, anemia, uremia, high fever, diabetes, and rheumatism.

3. The *office of the Columnæ carneæ* is: To prevent too great dilatation of the ventricles, to regulate their contraction, and to prevent the auriculo-ventricular valves from being turned into the auricles.

5. Stomach. (*a*) *Functions:* To receive the food, to secrete gastric juice, to mix the gastric juice with the food, to digest the proteids, and to absorb such portion of the food as is ready for absorption.

(*b*) *Secretions:* The gastric juice. This is a thin, colorless fluid, acid in reaction owing to the presence of hydrochloric acid, specific gravity 1001 to 1010, and contains about 1 per cent. of solids (pepsin, hydrochloric acid, a curdling ferment, mucin, and salts).

6. The *saliva* (by its ptyalin) converts starches into dextrose. The *bile* assists in emulsifying and saponifying fats, and also in the absorption of fats; it also aids the pancreatic secretion.

7. The products of digestion find their way into the blood by two routes: (1) By the blood vessels of the gastrointestinal tract, which unite to form the portal vein, and (2) by the lymph vessels of the small intestine, which converge to empty into the thoracic duct. The water, inorganic salts, proteids, and sugar go by way of the portal vein to the ascending vena cava; the fats go by way of the thoracic duct to the junction of the left subclavian and internal jugular veins.

8. The cerebrospinal system of nerves consists of the brain, spinal cord, and all the nerves connected with the brain and spinal cord; *i.e.* all except the sympathetic nervous system.

Its fibers are distributed to the voluntary muscles, the organs of special sense, and the parts endowed with sensibility.

9. *Fibrin* is found in the blood and lymph; *mucin,* in saliva and syuovial fluid; *chondrin,* in bone and cartilage; *leucin,* in the pancreas and spleen; *hippuric acid,* in the urine.

10. *Structures of doubtful or unknown function:* Spleen, thyroid, thymus, parathyroids, suprarenals, pituitary body, carotid and coccygeal glands.

HYGIENE.

1. *Foods are divided into:*

I. Inorganic. { Water. / Salts.

II. Organic. { Non-nitrogenous. { Carbohydrates. / Fats. / Nitrogenous—Proteids.

Example of each: *Carbohydrate,* sugar; *Fat,* fat of meat; *Proteid,* flesh of animals; *Salt,* sodium of chloride.

2. Physiological action of alcohol. *Nervous system:* Alcohol is first a powerful excitant, afterward a depressant; it increases the reflex activity of spinal cord, muscles, and nerves; in large doses it produces lack of co-ordination. *Circulatory system:* It stimulates the heart muscle and increases the rapidity and force of the heart beat; there is a rise of arterial pressure. *Respiration* is stimulated by small doses, and decreased by large ones. *Temperature:* Alcohol produces a sensation of warmth, and warms the extremities by causing the heart to pump hot blood from the center of the body to the cold parts. If used in excess the temperature rapidly falls, owing to increase of heat radiation and to depression of vital power. *Bodily metabolism:* Elimination of CO_2 is generally increased; the effect on absorption of O is not known. It adds force but not tissue to the body. *Elimination:* It is largely burnt up in the body, but in excessive doses it is eliminated by the breath, skin, kidneys, and intestines. *Digestion* is aided by moderate doses, but is disordered by large amounts. (From Hare's *Therapeutics.*)

4. *Nitrates* are generally due to the oxidation of organic matter of animal origin.

Nitrites generally indicate sewage contamination. The presence of nitrites should condemn the water; so should a marked amount of nitrates.

MATERIA MEDICA AND THERAPEUTICS.

1. Tannic acid. *Properties:* A light amorphous powder, with slight odor and astringent taste; it gets darker on exposure to air and light.

Action: Astringent and hemostatic; it will precipitate albumins; it is an antidote to antimony and some alkaloids.

Preparations: Glycerite of tannic acid, ointment of tannic acid, troches of tannic acid, and styptic collodion.

2. *Four spinal stimulants:* Strychnine, brucine, ammonia, and thebaine.

The action: They increase the irritability of the anterior cornua of the spinal cord.

5. *Three important hypnotics:* (1) Chloral hydrate; (2) Sulphonal; (3) Trional.

Indications: They are all used to produce sleep (when no pain is present).

Chloral hydrate produces a natural sleep, acts promptly but is of no service if pain is present; it also lowers the body temperature. It can be given for a long time without deleterious effect, but it may irritate the tissues and weaken the heart.

Sulphonal produces a natural sleep, but is of slow action requiring three or four hours to take effect; it is of no use if pain is present, does not irritate the tissues and weaken the heart, but is probably not so good for continuous use as chloral hydrate, though the two may replace each other for a time.

Trional is very similar to sulphonal, but is more soluble and acts quicker. Both sulphonal and trional are supposed to be safer than chloral.

CHEMISTRY.

1. OXYGEN. *Properties:* Oxygen is a colorless, odorless, tasteless gas, slightly soluble in water, heavier than air. It has a strong tendency to combine with other elements, and forms binary compounds with all elements except fluorine and bromine. Oxygen is necessary to the processes of life and combustion.

Preparation: (1) By heating potassium chlorate:

$$2KClO_3 = 2KCl + 3O_2$$

(2) By heating manganese dioxide:

$$3MnO_2 = Mn_3O_4 + O_2$$

(3) By the action of sulphuric acid on manganese dioxide:

$$2MnO_2 + 2H_2SO_4 = 2MnSO_4 + 2H_2O + O_2$$

(4) By the action of water upon sodium dioxide:

$$2Na_2O_2 + 2H_2O = 4NaHO + O_2$$

2 (*a*) There are five oxides of nitrogen known: Nitrogen monoxide, N_2O; nitrogen dioxide, N_2O_2, or NO; nitrogen trioxide, N_2O_3; nitrogen tetroxide, N_2O_4, and nitrogen pentoxide, N_2O_6. Of these, the trioxide and the pentoxide form acids.

(*b*) Carbonic acid, formula H_2CO_3, does not exist free, but is decomposed as soon as liberated into CO_2 and H_2O. Carbon dioxide, CO_2, is often (improperly) called carbonic acid; but this could hardly happen on an examination paper in chemistry.

3. Magnesium resembles zinc and cadium:

$$MgCO_3 + H_2SO_4 = MgSO_4 + CO_2 + H_2O$$

4. (*a*) *Alums* are double sulphates of the alkaline metals and the aluminum or iron group.

Four important alums: Aluminum potassium sulphate; aluminum ammonium sulphate; ferric sodium sulphate, and chromic ammonium sulphate.

(*b*) For Ehrlich's diazo reaction two solutions are required: (1) A saturated solution of sulphanilic acid in a mixture of 50 c.c. of hydrochloric acid and 950 c.c. of water, and (2) a 0.5 per cent. solution of sodium nitrite.

To make the test, 1 c.c. of (2) is added to 40 c.c. of (1), and the mixture thoroughly shaken. Equal quantities of this mixture and the urine to be tested are shaken together in a test tube, and 1 c.c. of ammonia is then floated upon the surface, when, in an affirmative result, a red band is formed at the junction of the fluids.

Its diagnostic value is uncertain. Von Jaksch "disclaims for this test any clinical importance whatever." Others have claimed that the reaction is pathognomonic of typhoid, but it has been found in other diseases besides typhoid—namely, phthisis, pneumonia, measles, scarlet fever, smallpox and malaria.

5. (*a*) The answer to this question will depend upon the text book used by the student (or examiner). Witthaus puts arsenic in the same group with nitrogen, phosphorus, and antimony; Remsen, in the same group with nitrogen, phosphorus, antimony, and bismuth; Simon, in the same group with antimony, tin, gold, platinum, and molybdenum; Holland, in the same group with antimony and tin.

According to the first of these groupings the arsenic group is trivalent or quinquivalent; with hydrogen non-acid compounds are formed, composed of one atom of the element in the gaseous state with three atoms of hydrogen; two oxides are formed, the trioxide and the pentoxide; they are poisonous.

(*b*) $2CH_2Br.COOH + Ag_2 = 2AgBr + C_2H_4(COOH)_2$
(Bromacetic acid) (Succinic acid)

$CH_2OH.CH_2OH + 2O_2 = 2H_2O + COOH.COOH$
(Ethene glycol) (Oxalic acid)

6. Urea is the end product of the proteid metabolism of the body. This metabolism is chiefly carried on in the muscles. It is not known in what form nitrogen leaves the muscles, but it is believed that the final products of muscle metabolism are ammonia and sarcolactic acid. Hence it is probable that nitrogen leaves the muscles as ammonium lactate. The tissues convert combinations of organic acids and ammonia into carbonates; these are dehydrated in the liver, so that ammonium carbonate becomes ammonium carbamate, and this by further dehydration becomes urea. The following formulæ show this relationship, and how the loss of one molecule of water converts ammonium carbonate into carbamate, and the loss of a second molecule of water produces urea:

$CO<^{O.NH_4}_{O.NH_4}$ $CO<^{NH_2}_{O.NH_4}$ $CO<^{NH_2}_{NH_2}$

NH_4 Carbonate. NH_4 Carbamate. Urea.

7. *Acholia* is absence of the secretion of bile.

Cystin is (chemically) diamido-beta-dithio-dilactic acid. It is found in urinary sediments and calculi.

SURGERY.

4. EMPYEMA. *Etiology*: Wounds, injuries, pleuropneumonia, direct extension of a suppurative process in the lung, abdomen, or neck. The bacteria will vary with the cause; *Diplococcus pneumoniæ* is the commonest; tubercle bacillus, staphylococcus, streptococcus, *Colon bacillus* may also be present.

Pathology: The organisms causing it are pneumococci, streptococci, staphylococci, tubercle bacilli, *Bacillus coli*, and actinomycosis.

The physical signs are those of fluid in the pleural cavity; that side does not move well, the percussion note is dull, there is absence of breath sounds, vocal fremitus and resonance are diminished. Left alone, an empyema may burst through an intercostal space, usually the fifth. The lung is collapsed in extent according to the amount of pus. The pleura, at first covered with lymph, soon becomes covered with layers of granulation tissue, the deeper part of which is converted into fibrocicatricial tissue, and the lung itself also undergoes some fibroid change. If the pus is let out early the lung and pleura soon expand, but if allowed to go on the infiltration of the lung and the density of the scar tissue covering it hinder expansion. Nature attempts to remedy this in various ways. (1) The other lung expands and pushes the heart over to the opposite side; (2) the chest wall falls in, the intercostal spaces are obliterated, and the spine is curved, with its concavity toward that side; (3) the abdominal viscera are pushed up; and (4) exuberant granulations form on the pleura. If a cavity still remains an operation is necessary.

Symptoms: Fever, sweats, chill, diminished breath sounds and vocal fremitus, impaired mobility of chest, dullness on affected side, heart displaced to opposite side, leucocytosis.

Treatment: Aspiration, drainage, irrigation, resection of ribs (Estlander's operation), or resection of chest wall (Schede's operation).

8. The *various dislocations of the shoulder joint* are: (1) Subcoracoid—forward, inward, and downward. (2) Subglenoid—downward, forward, and inward. (3) Subspinous—backward, inward, and downward. (4) Subclavicular—forward, inward, and upward.

The *special diagnostic signs* are: (1) *Subcorocoid*: The head of the humerus is felt below the outer end of the clavicle; there is little or no shortening of the limb; the elbow is directed outward and backward.

(2) *Subglenoid*: The head of the humerus can be felt in the axilla; the arm is decidedly lengthened; the elbow is flexed, and there are signs of pressure on vessels and nerves.

(3) *Subspinous*: The head of the humerus is felt below the acromion process and behind; the arm is rotated inward, and the elbow is displaced outward.

(4) *Subclavicular*: The head of the humerus is felt below the clavicle; the elbow is far from the side, and the limb may be shortened.

Kocher's method of reduction is: to flex the forearm, press the elbow to the side, rotate the arm outward. Bring the arm forward and upward to a right angle with the body, then rotate inward, while the elbow is brought down over the body so that the fingers sweep the opposite shoulder.

10. *Osteomalacia* consists in a softening of the bone tissues; it is found in the fully formed adult bones; there is great possibility of bending or fracture of bones, with considerable deformity. It may prove a serious obstacle to parturition.

LEGAL MEDICINE.

1. *Railway spine* is defined as "the series of nervous symptoms developed from shock produced by a railway accident, or from the concussion produced by constant travel."

5. *Rigor mortis* is the condition of rigidity or contraction into which the muscles of the body pass after death. It begins at a period varying from about fifteen minutes to about six hours. It usually begins in the muscles of the eye, neck, and jaw; then the muscles of the chest and upper extremity, and last of all those of the abdomen and lower extremity are affected. It passes off in the same order in about twenty-four hours. It is said to be due to the coagulation of the muscle plasma.

PATHOLOGY.

1. (*a*) *Causes of fever:* Disturbance of the heat-regulating centers, either directly or by toxic substances circulating in the blood. These latter may come from bacteria, or may be due to disordered metabolism, or to chemical or mechanical injury of the tissues.

(*b*) *Effects of fever:* Loss of appetite, thirst, emacia-

tion, disturbance of function, the alkalinity of the blood is lessened; degenerative changes such as cloudy swelling, fatty degeneration, and coagulation necrosis may occur in the tissues, particularly in the heart, liver, kidneys, and muscles.

2. (*a*) *The causes of Hemoptysis:* Traumatism; certain organic diseases of the lung, especially tuberculosis, lobar pneumonia, bronchiectasis, gangrene, infarct, and cancer. Passive congestion, the result of heart disease, especially mitral lesions; rupture of aortic aneurysm; diseases profoundly affecting the blood, such as purpura, hemophilia, scurvy, and leukemia; ulcers, traumatic, syphilitic, or malignant of the trachea or larynx; and vicarious menstruation (very rare).

(*b*) *The causes of Hematemesis:* Traumatism; gastric ulcer; gastric cancer; venous engorgement of the stomach following cirrhosis of the liver, primary splenomegaly, or chronic heart disease; acute gastritis; blood dyscrasia, as in scurvy, purpura, severe infections, and grave anemias; rupture of aneurysm; swallowing of blood from nose, mouth, or throat; vicarious menstruation; hysteria.—(From Steven's *Practice.*)

PRACTICE OF MEDICINE.

2. (1) Very young children are attacked with varicella, whereas variola usually shows itself in adults. (2) Vaccinated children readily take varicella; not so variola, even in the modified form. (3) Children who have had varicella may contract variola, even soon afterwards; or the two diseases may coexist. (4) Varicella is noninoculable, whereas variola is notoriously so. (5) The eruption of varicella appears in twenty-four hours; that of variola not till the third day. (6) The febrile symptoms continue after the eruption appears in varicella; those of variola subside. (7) In varicella the spots come out in successive crops; this is never seen in variola. (8) The spots in varicella are unilocular, and collapse on being punctured; the spots in variola are multilocular, and do not collapse on being punctured. (9) In varicella the eruption is very irregular, and appears over the body generally; in variola it appears in groups of threes and fives, and is always seen on the limbs. (10) The papule in varicella is soft, and disappears on stretching the skin; in variola it is hard and shotty, and does not disappear on stretching the skin.—(From J. W. Moore's work on *Variola and Varicella.*)

OBSTETRICS.

2. *Presumptive signs of pregnancy:* (1) Progressive enlargement of the uterus; (2) Hegar's sign; (3) Braxton Hick's sign; (4) uterine murmur; (5) cessation of menstruation; (6) changes in the breasts; (7) discoloration of the vagina and cervix; (8) pigmentation and striæ; (9) morning sickness.

Positive signs of pregnancy: (1) Hearing the fetal heart sound; (2) active movements of the fetus; (3) ballottement; (4) outlining the fetus in whole or part by palpation; and (5) the umbilical or funic souffle.

A positive diagnosis can very rarely be made before the sixteenth week; often not till the eighteenth or twentieth week.

6. A *diagnosis of occipito-posterior position may be based* on: Finding the sagittal suture in the oblique diameter of the pelvis, the posterior fontanelle in the posterior half of the pelvis, the anterior fontanelle is easily accessible; the fetal heart sounds are heard far back in the flank, between the ribs and the crest of the ilium; the fetal head may be felt above the pelvic brim, and the fetal small parts are felt through the anterior abdominal walls of the mother, while the fetal back is not felt.

Subacute Meningitis a Complication of Respiratory Troubles in Children.—Clement Delfosse mentions subacute meningitis as a not infrequent complication of pneumonia and purulent pleurisy in infants. The organisms that most frequently are responsible for this complication are the pneumococcus and the bacillus of Pfeiffer. The child generally gives a history of frequent respiratory or digestive troubles, or of the eruptive fevers. The microorganisms seem to be especially virulent in the cases in which we have this complication. The cerebrospinal fluid is always turbid, the more so in the severe cases, and there are present the microorganisms and polynucleated cells. The cerebral lesions are most marked on the convexity of the cerebrum. The prognosis is very grave, and treatment has little effect on the disease.—*Journal des Sciences Médicales de Lille.*

The Symptomatic Expression Called Exophthalmic Goiter in Its Relation to the Function of Reproduction in the Woman.—A. Pinard, after giving the history of an interesting case observed by him, in which the symptoms of exophthalmic goiter appeared whenever the reproductive functions were disturbed, gives it as the result of his observations that the syndrome called exophthalmic goiter has an etiologic relation with ovulation and not with pregnancy. As soon as the harmonious rhythm of the reproductive functions is re-established the syndrome disappears. It would be premature to say that, engrafted on a nervous soil, we have an autointoxication resulting from a derangement of an internal secretion of the ovaries, not the thyroid.—*Annales de Gynécologie et d'Obstetrique.*

Health Reports.—The following cases of and deaths from smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, Public Health and Marine-Hospital Service, during the week ended October 1, 1909:

ON THE CONSTRUCTION OF AN EFFICIENT AND ECONOMIC DIET IN TUBERCULOSIS.*

BY HERBERT MAXON KING, M.D.,

LIBERTY, N. Y.

PHYSICIAN-IN-CHIEF LOOMIS SANATORIUM.

BEFORE formulating a standard dietary for the tuberculous invalid it is obviously desirable that some acceptable conclusions should be reached regarding a standard for the normal individual, and unfortunately there is not at present among physiologists a striking unanimity of opinion in this respect. Thus the practice of dietetics in tuberculosis is of necessity largely empirical.

Most standard dietaries, especially the older ones, are based upon the food values actually consumed by different classes of individuals living under varying conditions as to occupation. Thus in Voit's standard for a healthy man of seventy kg. doing medium work, he gives a protein requirement of 118 grams with a total of 3055 calories—the same man at hard work 145 grams protein and 3574 calories. In Rubner's standard for the same man the protein is 127 grams and 2868 calories at medium work, and 165 grams protein and 3362 calories at hard work. Atwater's standard is higher than either of the former in calorie value, but somewhat lower than Rubner's in protein for the same man under like conditions. (Quoted by Lusk in "Science of Nutrition," page 188).

These standards are at such striking variance with those reached by Chittenden, who gives 50 grams protein and 2500 calories as sufficient for a soldier at work (*Lusk, loc. cit.*, page 185), that one is forced to conclude either that the protein constituent of the average diet is vastly in excess of the body needs and, therefore, very likely harmful or that Chittenden's standard is altogether too low for safety. The fact, however, that Chittenden's men appeared to do very well upon this remarkably low protein diet (Chittenden in "Physiological Economy in Nutrition") is certainly an argument against the need of the relatively high protein value of the older standards. Be that as it may, it is highly improbable that the ordinary individual will, from choice or experience, select Chittenden's standard on the strength of any argument which has yet appeared. In any case in the construction of a ration for the convalescent from a wasting disease it is safer to somewhat overestimate than underestimate the food requirements. To combat the inanition produced by the acute or advanced phases of tuberculosis, hyperalimentation seemed a reasonable and proper measure, while an actual and relative increase in the protein constituent of the consumptive's dietary seemed particularly desirable. That such a practice has in the past been carried to an absurd and harmful excess there can be little doubt. The immediate results of such treatment as shown by weight gain were flattering, but the ultimate injury both to the organs of digestion and elimination has so often proven disastrous that the "stuffing process" has, so far as I am aware, been entirely abandoned in institutions and among physicians who have much to do with the treatment of tuberculosis.

Unfortunately, however, medical tradition lingers a long time in the lay mind and in popular literature, and it is still a matter of common observation to find the tuberculous invalid relying upon his own initiative, forcing down eggs and milk in addition to his three hearty meals long after his weight has reached normal and when there is no possible excuse for a superabundant diet.

The wasting of consumption, it must be remembered, is not the result of lack of food for, as a rule, these patients have been in the habit of taking a sufficient diet prior to their illness, and are sufficiently supplied during the period of their disease, despite all that has been said to the contrary. It is the result rather of the grave functional disturbance incident to the toxemia of the disease. Digestion and assimilation are perverted or more or less interrupted, and until chance or proper treatment has effected an efficient remedy for this condition, all the food in the world will not control emaciation.

It is obviously impossible, even if it were desirable, within the limits of the present discussion to consider the many and various dietetic needs which arise in the treatment of advanced and complicated cases of tuberculosis. I shall, therefore, here confine myself to a discussion of a suitable dietary for the average sanatorium patient who may for present purposes be considered a convalescent—a suitable diet for whom does not vary greatly from that of the same person in health.

It is desirable to consider the subject first from the standpoint of efficiency and second from that of economy. It is plain that to start with we must adopt a working standard of some sort, whether it be based upon experience or purely theoretical grounds. To arrive at such a standard we must take into consideration the following facts which experience teaches.

(*a*) Men of the same respective age and weight seem to require a larger diet than do women.

(*b*) All other conditions equal, a larger diet is apparently required by persons under thirty years of age than is the case after that period.

(*c*) The laboring classes, *i. e.* those who earn their living by muscular work require more food than is the case with those living a more sedentary life, and in a certain measure the dietetic habits

*Read in abstract at the Annual Meeting of the National Association for the Study and Prevention of Tuberculosis, in Washington, D. C., May 13 to 15, 1909.

necessitated in the first place by occupation persist after occupation distinctions are removed.

(*d*) The urban dweller consumes a larger relative amount of animal food and therefore derives a larger percentage of his energy from the protein constituent of his diet than is the case with the country dweller. This, of course, applies only to the higher orders of civilization.

With these points in view and bearing in mind the wide individual variations which occur in all classes, we may assume for present purposes the following standards, applicable to ambulant cases of comparatively quiescent tuberculosis under sanatorium treatment:

(1) For young adult men of the "working class" on very light exercise from 2800 to 3200 calories, of which from 110 grams to 125 grams shall be protein.

(2) For the same class on five or six hours' vigorous exercise (sawing or chopping wood, working with shovels, pickaxes, barrows, etc.), from 3100 to 3600 calories, of which 125 grams to 140 grams shall be protein.

(3) For women of this class 200 calories and approximately ten grams protein may be deducted in each case.

(4) For young adult men, whose occupation has been more sedentary—*e. g.* clerks, bookkeepers, tailors, students, etc., on moderate exercise (walking from one to three hours daily) 2600 to 3000 calories of which not over 115 grams need be protein.

(5) For women of this class not to exceed 2500 calories and 100 grams protein.

(6) For older patients, a slight reduction in calorific value and a considerably lower protein constituent are desirable in each case.

(7) For the country dweller a somewhat larger bulk, without increase in protein value is usually desirable, all other conditions being similar, than is the case with the patient from the city.

Diets constructed on these standards in two divisions of the Loomis Sanatorium during the past year have proven more satisfactory than any which have been previously employed.

During the fall and winter of 1905 and 1906 in the course of some dietetic studies conducted at the Annex of the Loomis Sanatorium, a standard diet considerably larger than any of the above was used. We were still laboring under the tradition that hyperalimentation was desirable in the treatment of tuberculosis. Our standard during that period was protein, 166 grams; fat, 214 grams; carbohydrates, 323 grams; calories, 3955. Patients seemed to do very well on this diet. Weight gains were satisfactory, but digestive disturbances were not uncommon, and when I reported the results of our observations at the 1906 meeting of this Association, I expressed the doubt then that the protein constituent of our dietary was excessive. (Transactions of the National Association for the Study and Prevention of Tuberculosis, 1906.)

In the spring of 1908 we instituted a complete change in régime at the Annex and somewhat later at the Intermediate Division of the Loomis Sanatorium. Competent dietitians were given charge of the ordering and preparation of the food. The dietaries were constructed from prescription and accurate records were kept of all food actually consumed.

Before proceeding with a summary of the dietetic studies, which were based upon this change in régime, I may say in explanation that the Annex is a division of the Sanatorium intended to reach early, favorable, ambulant cases of tuberculosis, financially unable to meet a self-sustaining rate of charge. This division has a capacity of forty patients equally divided as to sex. Of the forty beds twenty-three are entirely free, while for the seventeen remaining a nominal charge of $5 per week is made. During the past year of the patients treated at the Annex there were 15.9 per cent classified as "incipient" upon admission, 47.6 per cent "moderately advanced" and 37.4 per cent "far advanced." Almost all of the Annex patients come from the "working classes" and are accustomed to manual work. In the course of their treatment work requiring considerable muscular exercise is prescribed in graduated doses —primarily as a therapeutic measure on the excellent plan devised by Doctor Patterson of the Brompton Hospital Sanatorium at Frimley, England.

The Intermediate Division of the Loomis Sanatorium is intended to be self-supporting, but on a basis of strict economy. It is intended to reach a class of patients whose means are limited, but who do not wish to accept charitable assistance. Only ambulant and favorable cases are admitted to this division. For the most part the patients are recruited from among convalescents who have taken the first period of their "cure" in the main division of the Sanatorium, and whose financial resources require close economy during the final term of their sanatorium residence. There is a capacity in this division for fourteen patients, also equally divided as to sex. They comprise for the most part, young clerks, stenographers, students, housewives and occasionally young professional men and women. Each of these divisions of the Sanatorium is conducted as a separate and independent unit, thus affording opportunity for comparative studies as to efficiency of diet and economy of administration.

At the Annex the new régime was begun early in June, 1908. It required some time, however, to complete the organization and get into good running order, so to speak, and prior to August 1st I do not consider the data reliable. In the meantime, however, we had determined by experiment that approximately 3000 calories with 130 grams protein was a very safe working standard when the average was considered of all the forty patients, twenty of whom it will be remembered were women, and a few of whom were children. Most of the patients were on from two to four hours' work, some of the men reaching six hours' hard work, while, of course, a certain percentage were always on more or less complete rest.

For the nine months beginning August 1, 1908, the average diet of all the patients actually worked out per capita per day: Protein, 131 grams; fats, 113 grams; carbohydrates, 385 grams; calories, 3166. The patients were made to eat slowly and advised to satisfy their hunger, but not to attempt a "stuffing process." Three regular meals were served, the heartiest at midday. An intermediate diet of about half a pint of skimmed milk was given twice daily, and during the cold weather cocoa took the place of the skimmed milk in the afternoon. No whole milk was used as a beverage, the cream being separated was used with cereals, coffee and desserts.

Somewhat to my surprise neither the fats nor proteins varied as much as I had expected with the seasons. There was a very slight increase in the consumption of fats during the colder months, but no sustained ratio in that respect in the case of proteins, while the total calories remained substantially the same. (See summary Chart I at end of

article). As might be expected there were some wide individual variations from these averages. Some persons are naturally large eaters; others again, absurdly small eaters. For instance, one patient frequently exceeded 4000 calories with 160 grams protein, while his weight remained practically stationary. Again a very well-nourished young woman never exceeded 2000 calories nor 100 grams protein, yet persistently gained in weight.

On the whole, this standard has seemed to meet the requirements of the class of patients treated at our Annex remarkably well. Weight gains have been fully as satisfactory as upon the older and larger standards, while digestive disturbances have been practically unknown. Under the old regime it was the exception to have less than four or five patients at a time temporarily confined to bed from causes usually traceable to dietetic errors, while under the new régime it is the rare exception to have one such case. Because of the different categories under which patients fall in the Sanatorium, as to amount and character of exercise, physical condition and dietetic habit, it was thought wise to separate the patients at the Annex into three groups and to observe and record their diets separately. This plan was carried into effect on November 1, 1908, and has proven both interesting and advantageous. The new comers and small eaters are placed at one table by themselves at which my resident medical officer presides. After their dietetic habits have been observed and, when necessary, corrected and they have been given light exercise they are graduated to another table, over which the nurse presides. The third table is made up of the "working corps" and large eaters, over which the business superintendent presides. The first and second tables do not vary in any marked degree as to the actual average food consumption, while, as might be expected, this average is considerably increased at the "work table."

For instance, the records for February, 1909, show the following average food consumption for the three tables, respectively:

FEBRUARY, 1909

Table I		Table II		Table III	
Protein	120 gms.	Protein	129 gms.	Protein	138 gms.
Fats	106 gms.	Fats	114 gms.	Fats	123 gms.
Carbohydrates	361 gms.	Carbohydrates	390 gms.	Carbohydrates	432 gms.
Calories	2,958	Calories	3,188	Calories	3,444

During February the patients at the "work table" (Table III) were all men working from two to six hours daily at timber thinning, *i. e.* cutting, sawing and piling cord-wood. The patients at Table II were of both sexes on moderate exercise, consisting chiefly of walking and "camp duty." Those at Table I were for the most part, of course, at rest or on very light walking exercise. During that month of a total of forty-one patients all but nine made substantial weight gains.

In our Intermediate Division approximately the same relative percentage of "incipient," "moderately advanced" and "far advanced" cases, respectively, obtained among the patients treated during the past year. The class differences between the patients treated in the Intermediate Division and those at the Annex will be borne in mind.

With but occasional exceptions all of the patients in this division were on moderate exercise, consisting of walking, snow shoeing, etc., from one to four hours daily.

The dietetic data in this division are accurate and reliable from December 1, 1908. (See Summary Chart II, page 637.) The difference in amount of food consumption between these two divisions of the Sanatorium is remarkable. In partial explanation of this difference it may be noted that nearly all of the patients in the Intermediate Division were up to or above their average respective weights when in health. The character of the exercise taken by these patients required the expenditure of less energy, and habitually large eaters were comparatively exceptional. Nevertheless, class peculiarities probably more than any other one factor account for the difference. I may add that in the Intermediate Division much more care was taken to make the table esthetically attractive and the service dainty than was the case at the Annex, and this point is significant in view of the results.

The average food consumption per person per day in our Intermediate Division for the five months from December 1, 1908, actually worked out as follows: Protein, 104 grams; fats, 106 grams; carbohydrates, 306 grams; calories, 2662. Thus it will be seen that the average daily food consumption by each patient in this division was more than 500 calories and 27 grams protein less than was the case at the Annex. So far as they could be attributed to diet, nevertheless, the therapeutic results were equally satisfactory in both cases. Weight gains, wherever weight was deficient, were all that could be desired and digestive disturbances were of exceedingly rare occurrence. Comparing the weight gains of the men with those of the women I found that the former did better than the latter and it occurred to me that it would be of interest and possibly advantageous to ascertain the relative food consumption of the two sexes—accordingly, beginning April 1st, we placed the seven men at one table and the seven women at another. For the month of April, 1909, the daily average food consumption per patient at the two tables, respectively, worked out as follows:

Men		Women	
Protein	114 grams	Protein	94 grams
Fats	102 grams	Fats	79 grams
Carbohydrates	351 grams	Carbohydrates	264 grams
Calories	2,850	Calories	2,201

It will thus be seen that at our Intermediate Division during this month the men consumed daily 646 calories and 20 grams protein per person more than did the women. Of the fourteen patients of both sexes all but one gained in weight during this month, the aggregate gain among the men being 5 kg. and among the women 3.820 kg. Of the patients in this division during April the average age of the men was 23 years and 9 months, that of the women 29 years and 2 months.

With a view of ascertaining the comparative results of differently proportioned diets upon the same individuals under varying conditions of rest and exercise the following experiment was made at the Annex of the Loomis Sanatorium this spring:

Four young men, patients in the Annex, volunteered for the experiment and by their faithful and cheerful cooperation made the conditions of the experiment possible. Following is a description of these patients as to their physical condition just prior to the experiment:

MacKenzie, twenty-two years of age, bookkeeper; normal weight ("Nylic Standard") 70 kg.; highest

known weight, 68 kg.; weight at beginning of experiment, 57.300 kg. Incipient lesion at right apex; sputa non-bacillary. Was on five hours' manual labor daily.

Knox, seventeen years of age; clerk; highest known previous weight, 50 kg.; weight at beginning of experiment, 51.320 kg. Incipient lesion at right apex; sputa non-bacillary. Had reached three hours' manual labor daily.

Fisher, twenty-one years of age; bookkeeper; normal weight, 63 kg.; highest known previous weight, 58 kg.; weight at beginning of experiment, 57.440 kg. Moderately advanced, but quiescent, lesions at both apices. Bacilli present in sputa. Had reached five hours' manual work daily.

Connor, twenty-two years of age; chauffeur; normal weight, 61 kg.; highest known previous weight, 60 kg.; weight at beginning of experiment, 58.380 kg. Incipient lesion at right apex. Sputa non-bacillary. Had reached six hours' manual labor daily.

These patients had the appearance of a very well-nourished and an unusually healthy group of young men. The experiment was begun April 1, 1909. The original plan was as follows:

1st week.—Rest, recumbent except for coming to meals and bathing. Moderate reading permitted. (What we term at the Sanatorium "comparative rest" as distinct from "absolute rest" when a patient is kept wholly in bed and treated like a typhoid patient.) An accurately weighed diet of 100 grams protein, 100 grams fat and a total of not to exceed 2500 calories.

2d week.—Two hours gradually increasing to five hours daily in two shifts of hard manual work. Diet same as during the first week.

3d week.—Work increased to six hours daily. Diet remaining the same.

4th week.—Work the same as in third week, but the diet increased to 150 grams protein, fat remaining the same and total calories advanced to 3000.

5th week.—Work to be increased and an effort made to increase the diet if possible to 4000 calories with 200 grams protein.

Through a misunderstanding of my orders a mistake was made at the fifth week. An attempt was made to increase the diet according to plan, but the men were taken off work and placed on "comparative rest" with the result that the full high diet was never reached and digestive disturbances necessitated the discontinuance of the experiment on the fifth day of this week.

Throughout the diets were varied as much as possible and the men were allowed any article of food desired so long as the day's total was kept within the prescribed limits. The men were weighed every day after breakfast. (Weights are net in all cases.) All urine was saved and accurately measured and examined as to specific gravity, abnormal constituents, indican, urea, etc., and a record of the daily total nitrogen excretion in the urine was kept in each case. (The Kjeldahl-Gunning method was employed in the nitrogen estimation.) As the daily excretion of urine seemed unusually large, especially in the case of MacKenzie, a careful daily record was kept of the fluid taken in each case after the ninth day. Fisher had had a slight albuminuria since his admission and this condition persisted throughout the experiment; otherwise the urines were practically normal. The details of this experiment may be gathered from the Table (Chart III), page 637. Charts showing graphically the daily nitrogen excretion by the urine and the nitrogen intake as estimated from the protein constituent of the food in each case are also appended (Charts IV, V, VI and VII.)

Summarizing the experiment as actually worked out we find that the diet during the *first week* was as follows: Protein, 100.7 grams; fats, 100.6 grams; carbohydrates, 317.7 grams; calories, 2649. No exercise except coming to meals and bathing was allowed. Slight constipation necessitated the use of mild laxatives during the week. At the end of the week Fisher had gained 1160 grams; MacKenzie, 200 grams; Connor, 280 grams; while Knox lost 220 grams. As was natural the men were somewhat restless, but slept well. For two or three days they felt underfed somewhat, but afterwards expressed satisfaction of hunger.

Second week.—The diet was slightly larger, but the protein constituent was the same: Protein, 101.2 grams; fats, 110.5 grams; carbohydrates, 356.7 grams; calories, 2904. Beginning with one and one-half hours' moderate exercise twice daily the men advanced gradually to six hours' hard work daily. All expressed a sense of well-being throughout the week. The food satisfied their hunger and there was no constipation. This week Fisher lost 660 grams; MacKenzie, 20 grams; Connor, 20 grams; while Knox gained 760 grams.

Third week.—No material change in diet: Protein, 100.5 grams; fats, 109.3 grams; carbohydrates, 344.3 grams; calories, 2836. During this week the men worked hard—six hours daily. Fisher lost 240 grams; MacKenzie gained 260 grams; Knox gained 1280 grams, and Connor gained 160 grams. All expressed perfect satisfaction with the diet and said that they felt better than at any time during the experiment.

Fourth week.—Protein constituent of the diet was increased 50 per cent, otherwise the diet remained practically the same: Protein, 150.3 grams; fats, 105.3 grams; carbohydrates, 344.3 grams; calories, 3007. The work was the same as during the third week, *i. e.* six hours daily hard manual labor. All lost in weight during this week—Fisher, 700 grams; Knox, 360 grams; MacKenzie, 440 grams, and Connor, 560 grams. Before the end of the week the men began to express a feeling of repugnance for meat and eggs from which most of the protein was derived. Their appetites were less and they felt overfed.

Fifth week.—The diet was still further increased. For the five days before the experiment was discontinued it averaged as follows: Protein, 151 grams; fats, 149 grms; carbohydrates, 436 grams; calories, 3795. As above stated the mistake was made of taking the men of exercise instead of increasing the work as I had intended, with the result that all were made ill from digestive disturbances (constipation, anorexia, and in one case vomiting and diarrhea). For the five days on this diet and rest Fisher lost 1400 grams, while the others gained as follows: MacKenzie, 600 grams; Knox, 200 grams, and Connor, 180 grams.

It will, of course, be observed that these men were naturally not large eaters, yet I think they represent the average healthy young man in their dietetic habits. It is, therefore, of some significance to note the amount and character of the diet upon which they seemed to do best, and it is further of interest to note that this diet (during the second and third weeks) was in calorific value very slightly

under our Annex Standard Diet, viz.: Annex Standard Diet, 3166 calories; most satisfactory test diet, 2900 calories, while in its protein constituent it was considerably less than our Annex Standard and almost identical with the standard at our Intermediate Division, viz.: Annex Standard Diet, 131 grams protein; Intermediate Division Standard Diet, 104 grams protein; most satisfactory test diet, 101 grams protein.

From a study of the Nitrogen Charts appended it will be seen that in a general way the nitrogen output in the urine diminished gradually for approximately fourteen days from the commencement of the experiment and then increased somewhat, although the protein constituent of the food was not materially increased until the twenty-second day. On this latter date it will be remembered the protein was increased 50 per cent and as would be expected there was an immediate response in the nitrogen content of the urine—somewhat delayed in the case of Knox and less marked in that of MacKenzie, but indicating the metabolism of a larger amount of protein in all cases.

It is worthy of remark that all of the men made substantial and very satisfactory improvements as to their pulmonary condition during the month of the experiment. Fisher lost his bacilli and in all cases the physical signs showed unmistakable betterment in the lesions.

I have already mentioned the wide individual variations from standards which are constantly met with in dietetic studies of this character. Some individuals seemingly require absurdly small diet upon which to maintain or even to increase weight as compared with others who persistently lose weight on just as absurdly large diets. As an illustration—during the winter of 1907-08, a patient in the main division of the Loomis Sanatorium, a young man very much under weight, with an extensive though quiescent infiltration in both lungs, had endeavored on his own initiative to increase his weight by a "stuffing process." Upon investigation his diet was carefully measured for three consecutive days and to my consternation I found that he was consuming daily, protein, 272 grams; fats, 271 grams; carbohydrates, 518 grams; calories, 5235. His weight at this time was 58.300 kg., so that he was taking a diet of 86.7 calories per kilogram of body weight, and still losing weight. His appetite by the way was remarkably good considering his enormous diet and the fact that he was on very limited light exercise. By cutting out the milk and eggs, which he had been taking his diet was reduced to approximately 3000 calories and 130 grams protein. Upon this diet he began slowly to regain his lost weight and needless to say he felt much better.

At the same time a woman with every appearance of robust health, weighing 78.600 kg., with an involvement (arrested) of the left lower lobe, was found to be gaining in weight upon a diet of, protein, 72 grams; fats, 62 grams; carbohydrates, 128 grams; calories, 1381, or upon 17.55 calories per kilogram body weight. In this case careful estimations of the food consumed were made for twenty consecutive days. In view of such apparently con-

SUMMARY CHART I

Showing daily food consumption and cost of raw food material per person per diem at the Annex of the Loomis Sanatorium. For nine months—August, 1908, to April, 1909, inclusive.

Month	Protein	Fats	Carbohydrates	Calories	Daily Rate per Person
August	129	110	377	3,107	$0.2675
September	128	112	353	3,013	.28
October	136	114	379	3,171	275
November	130	109	388	3,138	.296
December	133	116	405	3,284	.28
January	126	112	385	3,136	.33
February	129	114	391	3,192	.33
March	135	113	394	3,219	.31
April	132	115	395	3,230	.29
	1,178	1,015	3,467	28,490	$2.6585
Average	131	113	385	3,166	.2954

SUMMARY CHART II

Showing daily food consumption and cost of raw food material per person per diem at the Intermediate Division of the Loomis Sanatorium For five months—December, 1908, to April, 1909, inclusive.

Month		Protein	Fats	Carbohydrates	Calories	Daily Rate per Person
December		104	105	311	2,624	$0.36
January		101	112	293	2,664	.36
February		104	113	307	2,742	.32
March		107	111	313	2,755	.41
April		104	90	308	2,527	.38
		520	531	1,532	13,312	$1.83
Average		104	106	306	2,662	366
April	Men.	114	102	351	2,850	
	Women.	94	79	264	2,204	

CHART III

Showing Details of Diet Experiments

[1] Six days only.
[2] Record for six days only.
[3] Record for five days only.
[4] Excess of nitrogen in urine over nitrogen in food cannot be satisfactorily explained.

tradictory evidence as these cases present the endeavor to establish dietetic class standards seems difficult to say the least, and yet such sensational variations do not so much indicate different food requirements in different persons as they do the differences in individual capacity for metabolizing what food is eaten. Undoubtedly in the former of the two cases mentioned the great bulk of the food taken passed through the alimentary tract unchanged. That this was the fact indeed a study of the urine and feces demonstrated.

Before leaving this phase of the subject it is of interest to compare our present standard diet at the Annex of the Loomis Sanatorium with our former standard under the old regime, and with that which has been so thoroughly worked out by Bardswell and Chapman in England ("Diets in Tuberculosis," Bardswell and Chapman, Oxford Medical Publications).

Bardswell & Chapman Standard	Former Loomis Annex Standard	Present Loomis Annex Standard
Protein. . 150 gms.	Protein. . 166 gms.	Protein. . 130 gms.
Total calories.. 3,200	Total calories.. 3,667	Total calories. 3,200

It will be seen by this comparison that our present standard diet is in calorific value identical with that of Bardswell and Chapman, and somewhat lower than was the case with us formerly. It will further be seen that the protein constituent of our present standard is considerably lower than that of Bardswell and Chapman, and much lower than that of our former standard. I am convinced that the change which we have effected both in the construction of our dietary and in its total calorific value has been advantageous from every point of view. That we must supply in the food at least as many calories as the body expends in order to maintain health and weight is an obvious fact, but that we need supply greatly in excess of this amount, even in the presence of tuberculosis, is very improbable. Experience seems to teach that the smaller the balance over and above the actual requirements of the body the more satisfactory are the results.

For one unaccustomed to the work of constructing a dietary from prescription it is tedious and a little difficult at first to arrange a menu which shall represent approximately the desired food values. I have, therefore, appended at the close of this article a week's sample menu representing food values substantially such as our Annex standard calls for. I have taken one day's menu from each of seven months and given the average portions as actually consumed on the respective days. These menus (see Chart VIII) may possibly be found helpful to one who is called upon to prescribe a definite dietary for the tuberculous invalid.

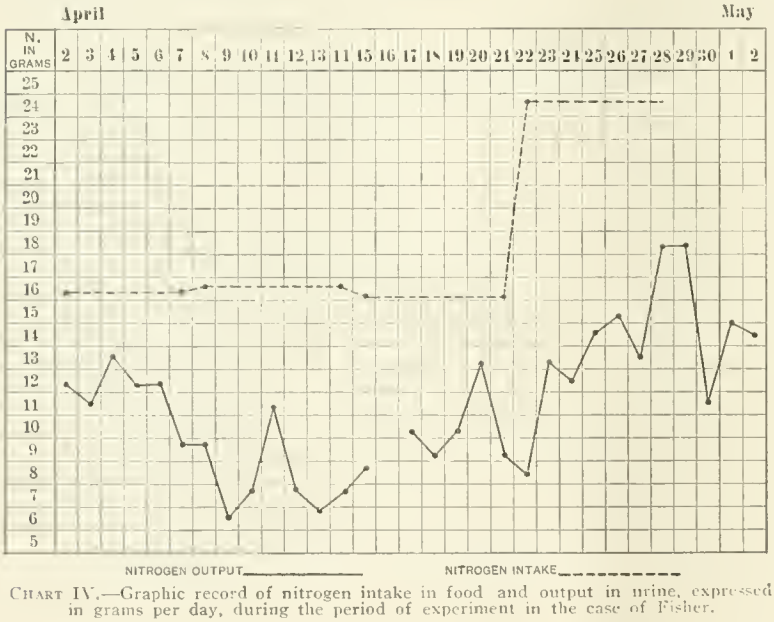

Chart IV.—Graphic record of nitrogen intake in food and output in urine, expressed in grams per day, during the period of experiment in the case of Fisher.

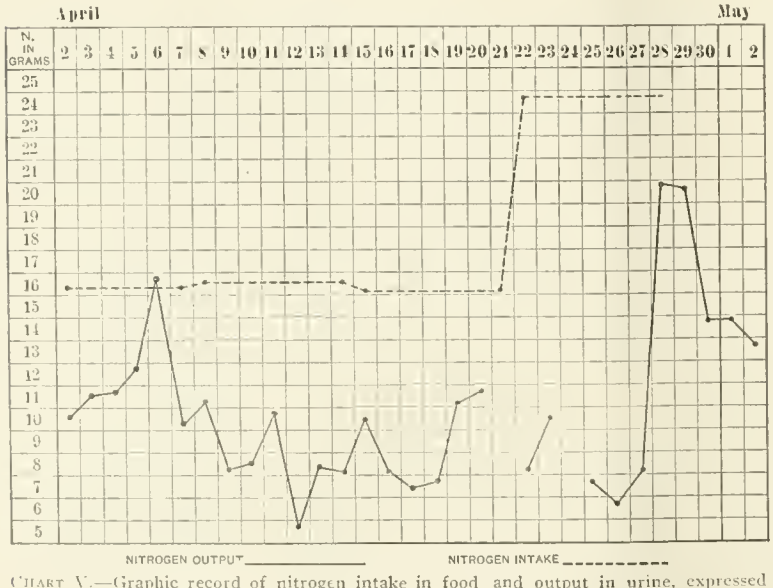

Chart V.—Graphic record of nitrogen intake in food and output in urine, expressed in grams per day, during the period of experiment in the case of Knox.

From the standpoint of economy it is highly important that the Sanatorium dietary shall be not only scientifically constructed to meet the requirements of treatment, but that extravagance and unnecessary waste shall be reduced to the minimum. As every one who has had experience knows full well, the Steward's Department is the chief item of expense in the administration of the Sanatorium, and when means are limited it it absolutely essential to the success of the institution that economy in this respect be practised. It must be remembered, moreover, that a poorly constructed or inefficient diet in such an institution is the worst form of extravagance, for it involves a worse than useless expenditure of means without conducing to the desired result; and in this respect it seems pertinent to observe that the average uninstructed or improperly instructed tuberculous invalid is no more fit to prescribe his own diet than he is to dictate his medicinal treatment. He will, as a rule, either grossly overeat or disastrously underfeed himself, or, what is almost as bad, he will overemphasize the relative importance of certain articles of food in consequence of which his diet is very apt to be greatly disproportioned as to its chemical constituency, and very likely to represent a cost out of all proportion to its therapeutic value.

In a brief discussion of this phase of the subject at the last International Congress on Tuberculosis (Transactions of the International Congress on Tuberculosis, 1908) I attempted to show from our records at the Annex of the Loomis Sanatorium how a dietary representing certain definite food values could be reduced in cost by intelligent dietetic management. Our experience in the Annex and Intermediate Division of the Loomis Sanatorium has proven beyond question that by substituting trained, educated dietitians for ordinary cooks and stewards, a sufficient saving in the cost of raw material and in its preparation for the table can be effected to far more than compensate for the increased salaries incident to such a régime, while at the same time the inestimable advantage is gained of having a much more scientific, wholesome and attractive diet. It will be seen by reference to Charts I and II that the cost of what have proved most satisfactory dietaries at our Annex and Intermediate Division worked out at 29.5 cents and 30.6 cents, respectively, per person per day (raw food material) for the past few months. In each case the saving effected under the new régime was something more than 10 cents per person per day over the previous cost of the same food value. The chief factor in this saving has, of course, been the elimination of waste, but other factors, small in themselves perhaps, have contributed to economy and are worth considering. For instance—eggs, which in America at least, are popularly, though erroneously, supposed to have some extraordinary merit in the treatment of tuberculosis, constitute at certain seasons of the year a most extravagant form of nourishment. For example, when eggs are worth 35 cents the dozen (and this is a very moderate winter price with us) the same amount of assimilable protein and fat can be purchased in the form of good beef for 50 cents as costs $1 in the form of eggs. In other words, eggs are just twice the cost of good beef, food value for food value.

Bardswell and Chapman (to the excellent and practical value of whose work I have already alluded) have admirably shown in how many little ways saving may be effected in the choice of food stuffs without in any way detracting from the nutrition value or attractiveness of the diet. Their work was done in England and of course their suggestions apply to that country particularly, nevertheless, many of the points which they make can be utilized to great advantage in this country. They show, for instance, that margarine has the same food value as butter, costs very much less, and for cooking purposes at least is in flavor and wholesomeness infinitely to be preferred to the ordinary "cooking butter;" that fats can be supplied in a dietary quite as attractively and more cheaply in some other form than cream, and thus separated milk may be used with economic and probably dietetic advantage also as a beverage

When large markets are close at hand it is comparatively easy to purchase with economic advantage. But most sanatoria are located more or less remote from great markets and for this reason it is all the more important that the selection of the food material and the construction of the menus shall be in the hands of competent and skillful dietitians if both sides of the problem are to be satisfactorily guarded.

With a view of ascertaining how the difficulties of the diet problem are being met in the various institutions for the treatment of tuberculosis in America I sent in February, a letter of inquiry to the Superintendents or Physicians in Charge of 214 such institutions in this country and in Canada. Among the questions asked in this letter were the following:

(*a*) In whose hands is the arrangement of the menus?

(*b*) Does the physician in charge control the dietary?

(*c*) Do you employ trained dietitians?

(*d*) Is any attempt made to control the chemical constituency of the food?

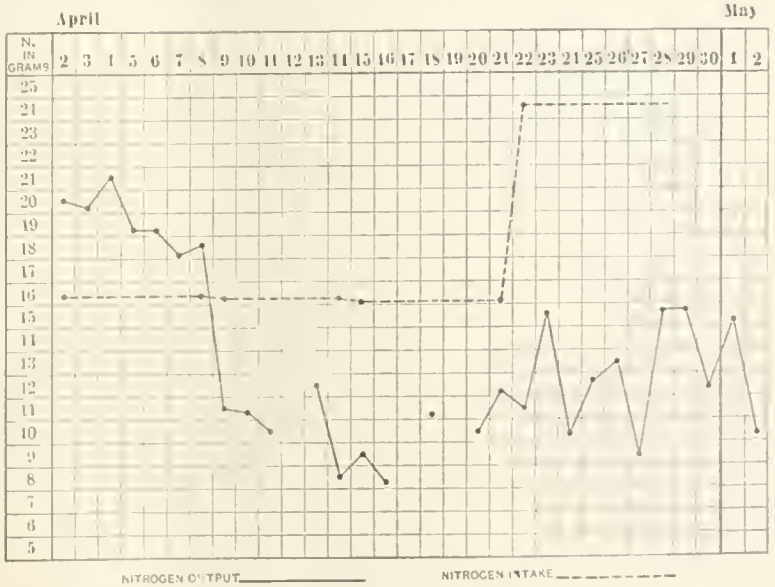

CHART VI.—Graphic record of nitrogen intake in food and output in urine, expressed in grams per day, during the period of experiment in the case of Mackenzie.

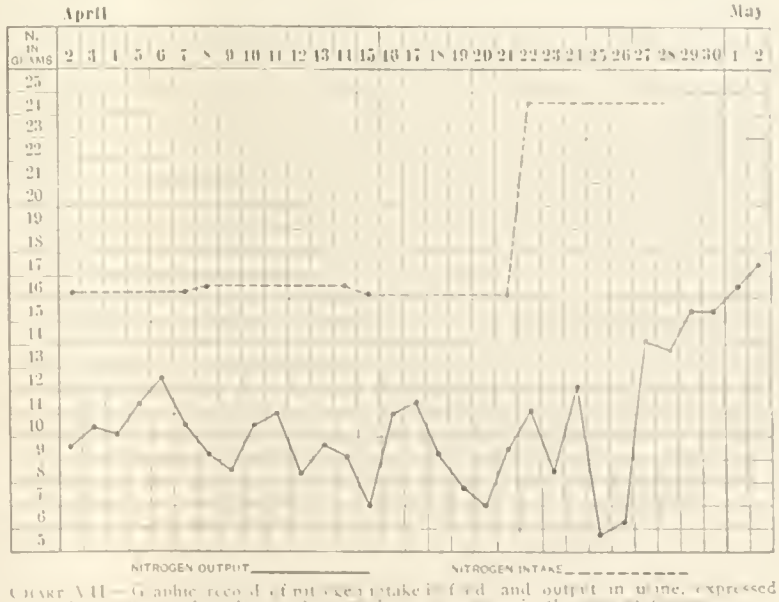

CHART VII.—Graphic record of nitrogen intake in food and output in urine, expressed in grams per day, during the period of experiment in the case of Curtis.

(*c*) What is the cost of raw food material per person (including employes) per day?

From the 214 letters sent out I received 130 replies. Five of these replies stated that for one reason or another the questions could not be answered. Of the remaining 125 in answer to question *a*, 85 stated that the menus were arranged by a matron or superintendent; 17 that the menus were arranged by a dietitian and in the remaining 23 they were arranged by the cook or chef. In reply to question *b*, 91 answered yes; one that the nurse controlled the dietary, while in the remaining 33 the question is not satisfactorily answered. In answer to question *c*, 17 replied that trained graduate dietitians are employed. In the remaining 108 institutions dietitians are not employed. In answer to question *d*, as might be expected, 17 replied that the chemical constituency of the diet is controlled. In 20 cases it is "partly controlled." In 76 it is frankly stated that no effort is made to control the constituency, while the question remains unanswered in 12. The answers to question *e* show that the cost of raw food material per person per day varies all the way from 22 cents to $2. Many of the institutions could not or at least did not answer the question. From those who did so it is learned that the cost of raw food material was found to be from 20 to 25 cents per day in two institutions, from 25 to 30 cents per day in two institutions, from 30 to 35 cents per day in nine institutions, from 35 to 40 cents per day in six institutions, from 40 to 45 cents per day in eight institutions, from 50 to 75 cents per day in eighteen institutions, from 75 cents to $1 per day in eight institutions, from $1 to $1.25 per day in nine institutions, from $1.25 to $1.50 per day in two institutions. Raw food material costs over $1.50 per person per day in three institutions.

In considering the results of this inquiry it must be remembered that these 130 institutions may be separated into several groups necessarily differing one from another both in their functions and requirements. Some of them are purely public charities supported by State, County or Municipality and intended to meet the demand of indigent patients only. Others are private philanthropies conducted on a semicharitable basis. Others again are private self-sustaining institutions, while a few are purely commercial enterprises.

Some admit only early favorable cases; others admit patients in all stages and still others are little more than homes for incurables; and finally a few are solely for the care of tuberculous infants and children.

Obviously, therefore, a fair comparison as to the respective cost of the dietary is quite impossible. One point, however, is emphasized by this inquiry, viz., the subject of the dietary in most sanatoria does not receive the attention which its importance merits, either from a medical or from an economic point of view.

Our ideas as to the dietetic requirements in tuberculosis are still to a large extent chaotic. It is a subject upon which there remains much work to be done and in the meantime we have to combat as best we can with insufficient data the fads and fancies of extremists; the exploitations of the patent food vendor and the absurd prejudices of the ignorant and half-instructed.

In conclusion I desire to acknowledge the invaluable cooperation and assistance in carrying out the above dietetic experiments and in formulating the data upon which this paper is based of my head dietitian, Miss Charlotte Strickland, and Miss Charlotte Young, dietitian at the Intermediate Division of the Loomis Sanatorium, without whose aid I could scarcely have carried out the work.

EARLY DIAGNOSIS OF MALIGNANT DISEASE OF THE LARYNX.

PATHOLOGY, PROGNOSIS, AND TREATMENT.*

BY WALTER F. CHAPPELL, M.D., M.R.C.S., ENG.,

SURGEON TO THE MANHATTAN EYE, EAR, AND THROAT HOSPITAL, NEW YORK CITY.

No subject demands or has received greater attention from laryngologists than malignant disease of the larynx. The recent writings of Delavan, Butlin, Glück, Semon, and others, would seem to have been the last words from the greatest authorities, but our "Omnipotent Council" have commanded something further on this important and interesting disease. The writer would not presume to present to this distinguished society a general resumé of the subject, but will ask you to accept his personal views and experiences.

The early symptoms in these cases are vague and the clinical picture obscure, so that the condition frequently remains unrecognized, irrespective of the fact that any hope of arresting the disease depends upon early diagnosis and treatment. How to get an opportunity to observe these cases in their earliest stages concerns us very much, as only too often they are not seen by competent observers until well advanced. Many patients are hoarse for weeks and months without any thought occurring to them that their condition may be serious.

Not unlikely they have consulted their doctor one or more times for a supposed cold before the patient comes under special observation. It is marvelous how casually the usual patient and doctor will treat a continued hoarseness; in fact, it is not uncommon for them to wait until some other symptoms appear before they think it worth while to get further advice. How different it would be if every doctor was able to examine the larynx intelligently and tell the patient at his first visit whether his hoarseness was due to a simple laryngitis, a growth, swelling, or an ulcer. This is exactly the place where very valuable time is lost. I think I can safely state that insufficient teaching of laryngology in most of the medical colleges of the past must bear the blame for this state of affairs. Personally I can state I did not see the larynx with any intelligence until five years after I graduated. About that time I spent six years in London, and on the continent, and had a good opportunity of meeting doctors from all parts of the world. I know positively that, with few exceptions, the physicians I met could not use the laryngoscope, though they had been in practice many years. The same condition of affairs exists to-day, and I do not believe one general practitioner in a hundred, who graduated before 1900, can examine the larynx satisfactorily. It is only two years ago I exhibited a woman before the Laryngological Association who had been treated for asthma by several well-known physicians for five years. A very easy laryngeal examination revealed a tumor as large as a hen's egg, swinging loosely on the top of the larynx. I could relate many similar cases, and believe there is not a man present who has not had some such experience. To my mind, the complete neglect of some practical knowledge of the larynx by all medical colleges in the past is a matter of great regret. When the medical colleges the world over graduate men who can examine the larynx as part of their routine work, we will then have an opportunity to see nearly all these laryngeal tumors in their earlier stages.

I am happy to state that Columbia University and some other medical colleges in New York have undertaken to give this practical instruction to all their students. The fourth year men of the College of Physicians and Surgeons, who come to me for clinical instruction, are made to realize the importance of continued hoarseness in adults and children, and during the past two years all our graduates have been able to describe the condition of the larynx intelligently. I do not believe this influential society could do a greater work than to enlist all its members in a crusade for better education in laryngology among all the medical colleges. In my belief, our brightest hopes must be centered on these lines, and nothing I say in this paper promises better results to the sufferer of laryngeal cancer than the plea for the better training of the general practitioner in laryngology.

Cancer of the larynx represents about one per cent of all carcinomata in general, and its diagnosis in the early stages is conceded by all writers to be especially difficult. According to Semon, not one single sign in the early stages of malignant neoplasm of the larynx is in itself so characteristic that it establishes with absolute certainty the malignant nature of the formation. The contour, the location, the condition of the surface, the color of the new growth, the condition of the surrounding tissue, the mobility of the vocal cord, the age of the patient, and certain subjective symptoms, all may and will assist the experienced eye in making the diagnosis, particularly when several of them jointly raise such suspicion, although none of them may be absolutely characteristic in the early stages. Nevertheless, these signs and symptoms taken together may have in the aggregate an essential bearing on the diagnosis, and suggest the cancerous character of the trouble. The early recognition of the disease in the majority of the cases is possible with the assistance of the laryngoscope. Sendziak says that laryngeal cancer in its very incipient stages may in most cases be diagnosticated exclusively on the basis of the laryngoscopical picture without resorting to the microscope. Certain contributory evidence may be con-

*Read before the American Laryngological Rhinological, and Otological Society at Atlantic City, June, 1909.

sidered in arriving at a diagnosis such as the predisposing factor of heredity. Certain professions and occupations which predispose to chronic catarrhal disturbances, and a history of excessive use of the voice, may turn the diagnosis in the direction of cancer before the process is far advanced.

For convenience of description we will follow the usual division of intrinsic and extrinsic cancer. We will discuss the diagnosis of the intrinsic variety first. Sex and age are recognized by all writers as having an important bearing on the nature of the growth, and will be accepted as generally understood and described in the leading text books of the present time. Hoarseness is by far the most frequent symptom in intrinsic cancer which leads the patient to seek advice. While preparing to make a laryngeal examination, the observer will likely make mental notes of the age and general condition of the patient and also the condition of the mucous membrane on the pharynx before the larynx comes into view. His chief interest will, in my opinion, then center on the location in the larynx of the trouble which is causing the hoarseness. If a tumor is found confined strictly to the true vocal cord the color, contour, and surface appearance will be noted. The color may be pink, red, bluish red, grayish white, or white in appearance. The benign growths may also present this same variety of colors. Therefore, too much dependence should not be placed on color alone, in deciding the nature of the tumor. The shape of the tumor may be round, flat, lobular, irregular, and dentated, and yet no variety of shape have any special significance as to its malignancy or non-malignancy; neither is there any special character to the surface form which might give us further information. Location on the cord should next fix our attention. The anterior half in a male over forty years of age may be favorable to non-malignancy; the posterior half to malignancy. The next point to consider is the attachment of the growth to the cord. Does it sit on the cord without seeming part of it, with a base possibly smaller than the crown and with no surrounding redness and infiltration, or does it seem to form part of the cord with a thick base, the immediate parts being red and infiltrated? The former description is suggestive of a benign growth; the latter of malignancy.

Our next consideration should be the mobility of the affected cord. This, in my experience, is one of the most important symptoms in our diagnosis, as I have never seen a malignant growth on the true vocal cords which did not, even in the earliest stages, produce some loss of motion in the affected cord. This may not be apparent at the first examination, but I am not satisfied on this point until a number of examinations have been made, and some at the latter part of the day, after the patient has been working, or using the voice. At this point I would like to state that in these early cases we cannot be expected to give a final verdict in a doubtful case after one examination. It is my custom in doubtful cases to keep the patient under observation for a week before giving my final decision. Considerable diagnostic significance is attached by some to a slowly and constantly increasing dyspnea, which depends upon the more or less impeded mobility of the affected vocal cord. Sendziak considers this symptom as pathogenic, to a certain degree, of cancer of the larynx. It is a fairly early symptom if the cancerous infiltratum begins in the region of the arytenoid cartilage, or cricoarytenoid articulations.

Our next step in diagnosis would be a microscopical examination of a piece of the tumor. This should be easily obtainable in the class of cases I have described. If the report is positive as to malignancy, taken with the clinical symptoms I have described, I would be satisfied that we had a malignant tumor to deal with; if, however, the clinical symptoms, signs, appearances, etc., did not support the microscopical diagnosis, I certainly consider the clinical picture much more important and would be guided by it in the treatment of the case.

I have had a number of cases where numerous examinations of sections of the tumor were made by different observers, who all gave a positive diagnosis of laryngeal cancer. The clinical symptoms did not support these reports, and the subsequent histories have proved them to be wrong. I will tax your patience with the report of one case. We have the history, opinions of consultants, reports of microscopists, and, lastly, the present condition of the patient.

Mr. Blank, age sixty, consulted me in June, 1903, for a hoarseness of six weeks' duration, which had come on rather gradually during the excessive use of his voice, in directing men fighting a forest fire. Laryngeal examination disclosed a white growth, about the size of a French pea, on the margin and upper surface of the right vocal cord at the junction of the anterior and middle third. The surface of the growth had a granulated appearance and there was no thickening or infiltration of the neighboring tissues. One small red vessel could be distinctly seen running backward on the upper surface of the cord, which was otherwise perfectly white. The growth seemed to hang or sit on the cord, and did not seem to be part of it. The movement of the cord was not interfered with, in my judgment. There was no cough, pain, or any other laryngeal symptoms. The personal and family history was excellent and the patient had not been a heavy smoker. I made a diagnosis of laryngeal papilloma and this opinion was indorsed by Dr. Jonathan Wright, but Dr. Charles Knight, who saw the case at the same time, believed the growth was cancerous in nature, and based his report on his belief that there was some impairment of motion in the vocal cord. Dr. Wright and myself could not see that there was any difference in the movement of the two cords.

Mr. Blank was a man of unusual judgment, and, having thoroughly mastered all the writings on laryngeal growths, decided not to have the growth removed at once, fearing that operative measures might convert his innocent tumor into a malignant one. I offer no criticism on this decision. Later, Dr. Dundas Grant of London pronounced the growth a papilloma. About two years after I first saw the growth, I removed it at Caux in Switzerland. Two weeks previous to the removal, a well-known laryngologist of Lausanne pronounced the growth as surely malignant. As the tumor had increased very slowly and only from the free surface, with no infiltration of the surrounding tissues, I held to the original diagnosis of Dr. Wright and myself, of innocent papilloma. The removal was made with a Sajous scissor-handled snare, a laryngeal canula having been made for the purpose.

The tumor was sent to London to the Laboratory of the Medical Graduates College and Polyclinic.

Report ——— herewith some slides from the laryngeal growth of Dr. Chappell's patient. I think you will find them interesting. At first sight they appear to be sections of a simple and innocent pa-

pilloma. Careful examination, however, reveals the presence of epithelial "cell nests" in various places, and although it is true that such "cell nests" are occasionally seen in benign papilloma, I am inclined to the belief that the growth is a malignant one, in a very early stage.

(Signed) A. E. Hayward Pinch.

Dr. Wyatt Wingrave reported at the same time that the structure was that of a squamous papilloma. In New York the slides were examined and reports received from the following gentlemen: Dr. Jonathan Wright, who pronounced the specimen a simple papilloma. Dr. T. Mitchell Prudden said in a large part of the section both the epithelial cells and the connective tissue are much shrivelled, so that their minute characters cannot be made out. So far as the condition of the section permits of an opinion, which must be based largely on the topographical features, the growth is a simple papilloma. Mr. L. B. Goldhorn of the University and Bellevue Hospital Medical College says: "I return herewith the slide sent to me for diagnosis. From a purely morphological point of view, the specimen is an epithelioma, which, however, shows no evidence of active proliferation, and is therefore either at a standstill or of slow growth. After receiving the history, I first became a little doubtful. In many places the growth is simple papilloma, but there are areas which are unmistakably epithelioma. I have made a photomicrograph of the most typical infiltrating area, and shall consider it a favor to have you accept a copy."

The history of this case is a good sample of the different views which may exist from a clinical and microscopical standpoint in an early case of laryngeal tumor. I am glad to be able to report that there has been no return of the growth, now nearly four years since the operation. There is a small scar on the cord, hardly noticeable, but otherwise the entire larynx has a normal, healthy appearance.

My remarks, so far, have been confined to intrinsic cancers as observed on the vocal cords. The other situations for intrinsic cancers are subglottic, ventricular bands, ventricles of the larynx, and anterior surface and base of arytenoid cartilages. Malignant deposits in these situations often progress to a considerable degree before they are discovered. In many cases hoarseness is not an early symptom, and there is nothing else which is definite enough to cause the patient to seek advice. Possibly a little persistent stiffness or discomfort is the only early symptom noticeable. Slight localized pain or soreness is, in my experience, one of the earliest symptoms of cancer in the situation just described. On a laryngoscopic examination we usually find a fair sized bulging mass, varying in color, size, and shape, according to the location. The color, shape and appearance of malignant growths in these situations resemble very closely early syphilitic deposits, and I consider it very difficult to make a diagnosis and know that mistakes are not infrequent. Any focus found to be deeply imbedded in the mucosa and indistinctly outlined from the underlying tissue should awaken a suspicion of its being cancerous in character.

Jackson's bronchoscope has been of great aid to me in making the diagnosis. You can not only get a much better view of the tumor, but can also touch it and move it about, to a more or less degree. This increases your knowledge of the whole situation and enables us to remove at pleasure a piece sufficiently large to make certain that it will be representative of the tumor. In my opinion, the use of these tubes does away with the necessity of exploratory thyrotomy for diagnostic purposes.

A brief report of the following case will prove interesting. Mr. D., age fifty, consulted me in November, 1905. Personal and family history good. Three months previous had a severe cold and hoarseness that continued until he saw me. Loss of weight had been great, and the general condition was very bad. Laryngoscopic examination revealed a large mass involving the right aryteno-epiglottic fold and all the tissues above the ventricular band and posterior surface of the right arytenoid hung back into the esophagus. Numerous deep ulcerations appeared on the surface, several severe hemorrhages had occurred, and there was a great deal of dysphagia. The tumor, as a whole, had every appearance of an ulcerating epithelioma, but the history was so short and so many changes had taken place in the mass in such a short time that I thought at first it was syphilis of the laryngeal cartilages. I kept Mr. D. under observation for one week, running the iodide of potassium as high as six drachms per day, with no improvement. Just at that time the laboratory report of Dr. Jonathan Wright was handed to me, and was as follows: "This is evidently an epithelioma springing from the basal or germinative layer of the squamous lining of the mucosa."

Mr. D. lived in Philadelphia, and, acting on the report of the microscope and his non-response to the iodide treatment, I unwillingly pronounced his case one of cancer, sent him home and placed him under the care of Dr. Braden Kyle. Meeting Dr. Kyle about a year later I spoke of the case, and he said it proved to be syphilis and I made a good recovery.

A recent letter from Dr. Kyle reads as follows: "The case of Mr. D. was one that failed to respond to iodides and mixed treatment. I then used the compound wine of iodine, which further convinced me that the lesion was a specific one. I then used inunctions of mercury with excellent results." This case is of special interest as adding another to those which have been reported as cancer under a microscopic examination, and the subsequent history has proved the report to be erroneous.

Early Symptoms of Intrinsic Cancer. The epiglottis, aryteno-epiglottic folds, and arytenoids are the locations usually involved when we speak of the extrinsic cancers. Of course, the earliest warnings the patient would have depend somewhat on the location of the growth. Implication of the epiglottis causes cough and a little difficulty in swallowing and very early "slips" in swallowing, so that liquid or food enters the larynx at times. The first objective evidence of a new formation on the epiglottis appears on the true margin, and the relatively thin mucosa in the vicinity of this cartilage facilitates the early recognition of the growth, as well as the determination of its depth and its relations to the surroundings; cancer of the epiglottis being relatively easy to recognize. There are especial difficulties, however, attached to the diagnosis of laryngeal cancers growing from the ventricles of Morgagni, or those developing so deep within the larynx that they can be noticed externally only after the parts have been stretched and the tissues separated from each other. It is under these circumstances that disturbances of the mobility of the corresponding vocal cord become especially suggestive.

Implication of the interarytenoid folds causes hoarseness and dyspnea quite early. Glandular en-

largement is one of the earliest symptoms in cancer involving the arytenoepiglottic folds. In fact, it is not unusual that the discovery of a small lump on the side of the neck is the cause of the patient seeking advice. Owing to the lymphatic arrangement in the laryngeal region, glandular enlargement appears early in many extrinsic laryngeal cancers, and very late in intrinsic cases.

Pain is a fairly early symptom, due to pressure and not ulceration, which is usually slow in developing. I have nothing new to add to the differential diagnosis between cancer, syphilis, tuberculosis, etc. The greatest difficulty I have experienced has been between cancer and deep laryngeal syphilitic deposits. Every means at our disposal should be employed to exclude syphilis, and even then we may sometimes be mistaken.

Personally I have nothing new to offer on the pathology of this disease, but Dr. Jonathan Wright has given me the following synopsis of a paper he read recently at the New York Academy of Medicine:

Cancer of the larynx has the same structure in its various forms as cancer elsewhere. Neither in the larynx nor elsewhere is structure a sure guide to malignancy, because the structure is dead matter and malignancy is a living force which causes death. Malignancy depends upon vital dynamics. Structure is their incidental or by-product. Certain structure usually accompanies malignancy, but not always nor necessarily. Recovery from cancer is repeatedly reported, and more often observed clinically than microscopically, and has been demonstrated in the experiments on animals. While this is true of cancer everywhere, it is especially true of cancer of the larynx, as seen by laryngologists, because laryngologists more frequently have the opportunity of observing nascent cancer, tiny excrescences, or small ulcers of the cords causing hoarseness and alarm. Such growths usually present in miniature, if examined in their entirety, all the minute structure of larger growths, but because they less frequently prove fatal than the further advanced growths meeting the general surgeon, mistake in diagnosis is more frequently charged upon microscopist than clinician. The fallacy lies, not with them, but with the orthodox conception of the nature of cancer. Added to this, liability of error of a general nature, the preliminary microscopic diagnosis of laryngeal cancer has to be based on the exceedingly small fragments usually secured for microscopic examination, and upon pictures obtained through rapid hardening and staining. Such small fields offer no opportunity for the study of topography, but we have to depend on one or two suspicious appearances and the relation these bear to the clinical history and gross appearances *in situ*. If, then, as I have said, the complete picture in well-advanced cancer is not always a sure guide to prognosis, the one or two features present in a small bit of crescent-shaped tissue from a nascent cancer are, of course, still more fallacious guides.

Carcinomata in any part of the body cannot be considered as offering a cheerful outlook. In spite of the somewhat optimistic statement of one writer (Semon) "that he considered intrinsic cancer of the larynx, when discovered early, and radically treated, as offering a more favorable prognosis than cancer in any other portion of the body," I regret to say my personal experience has not been so favorable. Clinical cancer of the larynx is always serious, but a "microscopic cancer" may give a more favorable prognosis. In view of the constantly increasing evidence of the total unreliability of the microscope alone as a means of diagnosis in cancer of the larynx, one cannot but wonder whether it is not possible that some of the complete cures that have been reported were not, after all, cases of microscopic cancer. When such a man as Dr. Jonathan Wright expresses his doubts about the microscope and says, as he has to me, that he would not think of performing any serious operation on a growth in the larynx without positive clinical evidence of its malignancy, it is certainly time that this subject should receive more consideration at the hands of all our special societies.

Various degrees of malignancy are recognized in all cancerous growths and must be important factors in the prognosis. Heredity is another factor bearing on rapid or slow recurrence. The original site of the growth has a bearing on the prognosis, as does also early discovery, age of patient, and nature of operation.

Passing to the treatment of laryngeal cancer, which we are to consider only in its early stages, I wish to state that I do not propose to consume your time reciting the opinions of others, or the details of the various operations, as they are matters of record and well known to all. Some writers, in discussing the treatment, have made no distinction between the intrinsic and extrinsic cancers, which is an important division, not only from the standpoint of treatment, but also diagnosis and prognosis. This division allows a much clearer description and treatment of the whole subject. When a positive diagnosis of intrinsic laryngeal cancer is made, operative measures are the only means we should employ; all others fail to cope with the gravity of the disease. Thyrotomy, in my experience, possesses the greatest therapeutic significance in the management of the disease. It is suitable when the growth is limited to the vocal cords or the soft parts in the interior of the larynx. In regard to the postoperative security from recurrence, it is nearly equal in value to laryngectomy, whereas the safety of the operative intervention as such renders it infinitely superior to total or even partial resection of the larynx.

In a doubtful or suspicious case of laryngeal tumor, an exploratory thyrotomy is justifiable, although, as already stated, Jackson's tubes have, in most cases, removed the necessity of explorative measures. Personally, I would not consent to, or recommend laryngectomy in an early case of intrinsic laryngeal cancer.

Extrinsic laryngeal cancer is an entirely different matter, and must always be considered serious. In a patient under fifty-five years of age, when the cancerous tumor has been discovered early, total extirpation of the larynx should be advised, excepting when the new growth is confined to the epiglottis. Of course, the serious risk of the operation should be explained to the patient, and also the discomfort of wearing a tube, which he will be obliged to do.

From the point of view of recurrence, total resection of the larynx is superior to all other operative measures. After the patient is fifty-five years of age I do not advise the radical operation, even in early cases of extrinsic cancer. I believe the partial extirpation promises more for the patient. The kind of partial removal would depend on the location and size of the tumor. Complete extirpation of the

larynx has no attractions for me. It must, however, be recommended in certain cases, and when successful is a brilliant surgical triumph. A life may be saved, but I know of no more pitiable object than a person without a larynx.

PRECOCIOUS TERTIARY SYPHILIS: REPORT OF A CASE WITH MANIFOLD MANIFESTATIONS.*

By H. FRED LANGE ZIEGEL, M.D.,

NEW YORK.

While justification for the use of the terms which have been selected for the title of this report can be found in the works of Alfred Fournier, Eduard Lang, and Robert W. Taylor, nevertheless it is admitted that the phrase "precocious tertiary" is objectionable, because its use implies that the course of syphilis can be divided by time-rules into stages; whereas, what the successive phenomena of syphilis really represent is an evolution or progression. But the case to be reported corresponds so closely with a type-form accurately described by Robert W. Taylor that this somewhat objectionable terminology is retained.

After having defined a form of precocious tertiary syphilis in which cutaneous gummata and ulcerations develop immediately after the secondary symptoms, the American Syphilographer goes on to say that "tertiary syphilis may be rather less precocious than in the form just described. Toward the end of the first year of the infection, after the evolution of secondary manifestations, some patients become weak, anemic and lose flesh. One, several or many ulcers may appear on the scalp, the face or the extremities, and run an active and rapid course, showing great rebelliousness to local and general treatment and careful hygiene. In some of these cases there are concomitant bone, joint, pharyngonasal, and testicular lesions. The patient is and continues to be a sick man upon whom destructive lesions appear at short intervals. In most of these cases, after a very severe ordeal the patient gradually gains health and strength, and may be cured in the end."[1]

Conforming closely with this description is the case of G. F. B., 37 years old, infected postnuptially by his wife three and a half years ago. When first seen two years ago the patient stated that treatment during the year and a half following infection had not been thorough or methodical, and that for three months there had been present an ulcer of the leg. Examination showed on the postero-external aspect of the lower third of the right leg a circular, sluggish-looking ulcer with sharply defined edges and a dirty-yellowish purulent base. This ulcer healed promptly as a result of deep injections of the salicylate of mercury and local surgical cleanliness.

There next appeared a scalp manifestation diagnosed by Dr. Sigmund Lustgarten as a "precocious papular syphilide." This was very resistant to treatment and persisted for a long time in spite of active mercurialization and local treatment under Dr. Lustgarten's direction.

At this time the patient's general condition was not good, there being considerable loss of flesh and strength; and there were present deep ulcerations of the pharynx and on the tonsils. These throat manifestations reappeared from time to time, generally during intervals between courses of mercurial treatment. In fact, attempts to suspend even temporarily the exhibition of mercury always resulted in the appearance of new lesions.

If we continue, now, to enumerate chronologically the various manifestations, the fourth was a syphilitic stricture of the left nasal duct, with distention of the lacrymal sac, tearing, and unilateral conjunctivitis. Dr. Martin Cohen, who diagnosed and treated the local condition, reported that at this time fundus examination showed pallor of the disc on the temporal side, edema on the nasal side; dilatation of the veins; and some opacity of the vitreous humor.

Fifth, there appeared protuberances on the forehead—superficial gummata which ulcerated. These ulcers healed, reopened some months later, and healed again.

Sixth, there was a periostitis of both nasal bones.

Seventh, the patient came complaining that nasal breathing on the left side was obstructed; examination showed a swelling springing from the nasal septum and occluding the left nares. This gumma soon broke down, resulting in abscess formation, and a large perforation of septum which can readily be seen at the present time.

Eighth, bursitis and synovitis. The left ankle became swollen, impaired in function and very painful at night. Soon afterwards both knees became similarly affected. The patellar bursæ were considerably enlarged, and there was dancing patella. These hydrarthroses coresponded closely with Levin's description of "Synovitis of the Knee-joint as a Late Manifestation of Acquired Syphilis."[2]

Ninth. Periostitis of the heads of the tibiae, first on the right side and then on the left. This latter was very severe, totally incapacitating the patient for two weeks. During this time severe nocturnal pain was complained of: there were marked tenderness over the inner tuberosity of the head of the left tibia and severe pain on the slightest movement. The circumference of the legs, which was measured 4 cm. below the lower border of the patella, was 3½ cm. greater on the left side than on the right.

At this time, as on several occasions previously, inunctions were given instead of the injections, because of the large number of nodosities in the buttocks. Palpation of the gluteal regions gave the feel of bags of nuts.[3] So far sixty-eight deep injections have been given.

Tenth, there developed six months ago gummatous infiltration of the right testicle which was hard, nodular and twice its normal size. This, like the other manifestations, has been favorably influenced by the treatment.

Eleventh, synarthrositis. Six weeks after this report was submitted for publication, there appeared —following a month's intermission in the administration of mercury—tumefaction and tenderness over the first, second, and third chondrosternal articulations. The prominence of the first joint was considerable. Gratifying evidence of the specificity of mercury were the prompt retromorphous and ultimate disappearance of these swellings on resumption of the treatment.

A modified Wassermann test, performed by Noguchi about one month ago, was positive. Of course treatment is being continued.

The patient is now steadily gaining in weight and he has no complaint to make. Though he looks

*Patient presented before the Harlem Medical Association, June 2, 1909.

very pale, his hemoglobin is 84 per cent.; it has never been less than 60 per cent. In spite of the enormous dosage with mercury and the iodides, his teeth, gums, and gastrointestinal tract have remained in good condition. There has never been any albumin in the urine. Constitutionally, therefore, he has been tolerant to mercury. But the local reactions after injections have at times been very severe; however, only indurations and no abscesses have resulted.

Conclusions.—A patient with syphilis which had not been systematically treated began to exhibit, fifteen months after infection, tertiary manifestations which appeared in the following order: (1) Ulcer of the right leg; (2) papular syphilide of scalp; (3) deep ulcerations of tonsils and posterior pharyngeal wall; (4) stricture of the left nasal duct; (5) ulcers on forehead; (6) periostitis of nasal bones; (7) gumma of nasal septum, suppuration, and perforation; (8) bursitis and synovitis; (9) periostitis of heads of tibiæ; (10) gummata of right testicle; (11) synarthrositis.

Eduard Lang says that "when the gummatous deposits in early periods of syphilis are markedly conspicuous as regards both their number and rapid course, it is certainly proper to express this character of the disease by the term syphilis 'precox.'" Accordingly, the case just described may be spoken of as one of precocious syphilis.

In tertiary syphilis, as is well known, the lesions usually involve the deep-seated organs and tissues; not so in this case, in which the lesions have been superficial, involving chiefly the skin, mucous membranes, ocular appendages, cartilages, bursæ, periosteum, the testicle, and chondrosternal articulations.

The two noteworthy features of this case are, therefore, the early appearance of the tertiary manifestations and their superficiality.

THE CARE OF THE NURSING BREASTS—THEIR DEVELOPMENT DURING NEURASTHENIC PUBERTY.*

BY GEORGE E. ABBOTT, M.D.,

PASADENA, CALIFORNIA,

FORMERLY INSTRUCTOR IN THE NEW YORK POSTGRADUATE MEDICAL SCHOOL.

ON the one hand breast feeding seems so simple, so natural, so physiological, that no special interest is aroused by its consideration. On the other hand, its relations and complications are widespread and test the acumen and medical skill of the most experienced, necessitating the study of the past and present clinical history of the father and mother, the persuading of the fashionable mother to give up her selfish social obligations, in justice to the little stranger, and many other tasks.

Pardon me if I break away from the usual course of a conventional stated paper on Breast Feeding, and bring you some disconnected clinical pictures of its anatomy, physiology, pathology, and psychology, and find, if you can, anything of interest in them.

Picture to yourself, if you will, how carefully nature guards the vital points of our anatomy. Brain, heart, lungs, and reproductive organs are all encased or surrounded by bony bulwarks. The spinal cord is carried along a bony tunnel with spinous processes projecting in four directions. The main arteries, veins, and nerves are placed on the inner surface of the limbs, exposed, it is true, in the biped, but well guarded in our original quadruped existence.

Now the breasts are not vital to the mother, but are to the child and to the continuance of the race. Therefore, in order to protect and maintain at all hazards the nourishment of the child, nature tapped the subclavian artery and carried the main blood supply of the breast by the internal mammary artery down within the bony chest wall, then out through the intercostal spaces, and into the base of the glands, and thereby hang the following clinical pictures:

Some years ago I delivered a mother of her third baby. Her first child had good nursing; the second child had practically none; the mother complained of this to me, and said she hoped she would be able to nurse the coming baby. On examination I found the nipples well formed, breasts unusually good, glandular tissue abundant, but I also observed that the breasts were heavy and sagged downward and backward; so much, that on placing a straight edged ruler on the sternum, as she lay in bed, it touched neither breast.

It then occurred to me, that as the patient lay upon her back—as many mothers do much of their parturient period—the heavy, pendulous breasts carried the perforating arteries firmly against the ribs and thus cut off their arterial supply.

I explained this to the mother, and told her that if she would lift and constantly support her breasts and allow the blood to flow freely into them, I believed that she would have all the milk she needed. She had an abundance of milk and nursed her baby to full time. It is true that this was an extreme case, but in a minor degree it is a not infrequent clinical experience.

Allow me to add this suggestion also: A case in psychotherapy, which I am studying in Pasadena wherein the blood supply has been explained to another mother, with a request that instead of sitting up while nursing her child, she should lie upon her nursing side, giving the circulation the best possible advantage, and at the same time mentally direct the flow of the blood toward her breast for the sake of her little babe. I do not know as yet what the outcome will be.

Here is still another clinical picture in my anatomical collection. Some weeks since, I told a mother and her nurse, both easy-going housekeepers, that I would like her to nurse both breasts each time. She replied that "Dr. Blank's little book said it was not necessary, that one breast at a time was sufficient." It is always refreshing to have one's patient quote some high authority in contradiction to your orders; nevertheless, with as good grace as I could, and without knowing whether she quoted correctly or not, I asked her to leave me out of the question entirely, and allow Dr. Blank to remain in New York, and then use her own common sense, and judge for herself. That if she nursed her babe every two hours, as Dr. Blank and everyone else

*Read before the Pasadena Medical Society, May, 1909.

advised, in one case she would have one breast empty and close to her chest, while the other would be full, distended, and hanging as a heavy weight on her chest for from two to four hours. The next nursing would reverse the conditions. The second breast would be empty, while the first would be distended, heavy and drooping, with the result that in time she would have two large heavy, pendulous breasts to drag upon her the rest of her life.

If she nursed both breasts each time she would have two small, active, well-formed breasts, well placed, close to her chest, and a good physique all her life; she could take her choice.

At times, in the case of a small, undeveloped breast, I believe it is wise to allow the breast to become overdistended—now and then to secure a certain amount of hyperemia. The same is true of hot applications, and especially of the Bier vacuum glasses.

As you pass along my clinical picture gallery, I must call your attention to these two companion pieces, which so often make breast feeding possible or impossible: The first is a demonstration of the illogical application of breast massage, as almost invariably practised, and, I am sorry to say, taught by some of our latest text books, where, in order to relieve the congested and overdistended milk ducts of a "caked breast" the nurse is instructed to begin at the periphery of the gland and gradually force the milk to and out of the nipple. If we had to clear a house of its furniture, and the front hall was already crowded full of furniture, we would not begin in the rear rooms and press tables, lounges, and chairs harder toward the front door. We would first relieve the packed hallway, and then with ease clear one room after another.

The second picture shows the deft fingers logically massaging the nipple first, then the region of the areola, following this the body of the gland, and finally the periphery, and all done with a gentle touch and with a minimum of pain. Let the nurse try one breast one way, and the second breast the reverse, and let the patient be the judge of the best method.

Next to these are two other companion pictures, one of a mother presenting her breast to her child. The nipple is erect, congested, distended, hard, and covered with stiff, dry epithelium; the eager baby seizes the nipple, crushes it between its little gums, the epithelium cracks, and thereafter follow infection, pain, painful nursings, solutions of nitrate of silver, lead shields, ointments, and perhaps abscess. The companion picture shows preparatory care, gentle massage of the nipples with lanoline cream before each nursing; the nipples are now as soft and pliable as new rubber, yield readily to the gum pressure of the child, while the mother delights to welcome her baby again and again.

Somewhere here, there is a picture of a nursing mother berating her dairyman for allowing his cows to eat the wild turnips in the pasture or giving them sour silo, which she tastes in the milk, while at the same time she is cooking on the stove corned beef and cabbage, turnips and garlic. "What's good for the goose is good for the gander," but it isn't always good for the goslin or for the breast-fed child.

There is an interesting phase of breast feeding in the elective selection of breasts, in the single, as contrasted with the multiple fetus-bearing animals. The dog, cat, and swine have their many breasts arranged in a slightly diverging row along the abdominal wall, near the median line.

The single fetus-bearing quadruped, with the sternum comparatively near the ground, and with the intestines falling toward the diaphragm, as the mare, cow, goat, etc., elect to develop the last or pelvic gland and carry it well up between the hind legs, where there is the most room, while the biped, as man and the kangaroo, have developed the gland at the upper or sternal end of the multiple breast chain, where the infant may be carried in arms and nursed at the same time. The whale also, which uses its tail as its only weapon of defense, must have its baby near its head and away from danger during a battle, and therefore selects a sternal gland.

Physiologists tell us that the breast of the little child remains undeveloped and dormant until puberty, and even then, although the breasts develop it is almost entirely a matter of connective tissue, while the true gland tissue still remains practically infantile until conception takes place.

One can hardly believe this to be the case, when one sees every other reproductive organ, vagina uterus, and ovaries, all gradually developing, both automatically and physiologically through a series of years and gradually fitting themselves for functional duty. We know that the blood and nervous systems have a marked influence upon the breasts and breast feeding, and that these communicating channels also must be developed before maturity.

Is it possible to increase their development psychologically? I cannot expect you all to agree with me in the following psychological thought and practice, but hope that I may find one or two who may at least care to think about it. As one sees our school children come and go, one easily recognizes that this child and that, and that, are normal, well-developed children, their love goes out to their parents, to each other, to their dolls, to animals, to everything. They are already little mothers in physiological prophecy. Leave them alone; they will need no help in their development.

Here is another group that have all the "ear marks" and every other mark of an "old maid." I dislike extremely that term, but I use it to bring to your mind a psychophysiological portrait, well known to those who have studied the young. Almost of necessity, and without exception, they are destined to become "old maids," not "bachelor girls," that variety of genus homo, without whom life were hardly worth the living, and whose royal, generous mother hearts (mothers in every sense save in the physical definition) do more than their share of caring for and educating the little children of the world. These "old maid" children, unnourished, overstrung, nervous, dyspeptic, cranky; these little neurasthenic bundles of suffering humanity ought to have our kindliest sympathy and our most skilful care. Now, how can you better practise preventive medicine and, as it were, prevent neurasthenia, than by bringing these little girls' physiology up to the normal standard.

And when and how can one better bring their physiology up to normal than by seizing the opportunities of their period of puberty, when their whole system is to reconstruct itself, causing many of the tissues to struggle upward into healthy action or degenerate into aborted and irritating centers. Puberty is an elective period, a strategic point for the family physician and the specialist, the physiologist neurologist, and psychologist, the ramification of its opportunities would fill a long paper.

In closing, I have but one suggestion to make. Let the thoughtful physician counsel the mother to

be wise and warn her little girl of the change that will come upon her, encourage her to be glad of the coming development, and its possibilities of future motherhood; explain her menstrual periods; but otherwise leave the pelvic organs undiscussed until a later date. Secure the development of the pelvic organs by the reflex influence of the breasts.

Curiously enough the little child's mind may be in total ignorance of the logical step of cohabitation, impregnation, and parturition, and she may at once imagine herself the fully developed mother of her dolls; she has done this for many years already, in a childish way. But now we have an opportunity to produce a psychic effect of great value in our little menstruating girl, by encouraging her to nurse her tiny imaginary child. I said "imaginary child." Do not give her a cold, china-headed doll, nor one of those celluloid fetuses, nor even her rag baby, there is no possible opportunity for imagination with them. Let the mother make a long, narrow fold of a soft Turkish towel, warm it thoroughly, especially the doubled end, that will represent, in the little girl's imagination, the baby's head, and then place the warm towel inside the night robe against the little girl's breast, and tell her to nurse her baby and then go to sleep. Go away now and leave the little girl to her own thoughts.

Repeat this one or two evenings at each menstrual period for a year or two, and then if you see the overwrought nerves relax, the nervous reflexes lose their sting, the child's temper soften, her neck and limbs develop, and her whole physique round out, you will know that you have practised preventive medicine in that best of all medical fields, the childhood of the human race, and, in all probability, have added another "breast-feeding" mother to our national motherhood.

THE GREAT IMPROVEMENT IN MANY ADVANCED CASES OF PULMONARY TUBERCULOSIS UNDER SANATORIUM CARE.

By HORACE GREELEY, M.D.,

BROOKLYN, NEW YORK.

The general rule among sanatoria is to accept none but early cases of pulmonary tuberculosis, adjudging the care of the more advanced to be too unsatisfactorily and to rarely yield good results. But as it is known that a certain percentage of even those cases classed as incipient fail to improve and even decline under the best conditions, and as it is capable of proof (some of which I have now to offer) that at least a majority of patients with extensive pulmonary lesions and great constitutional depression resulting therefrom may be greatly benefited, and some have their disease more or less permanently arrested by a comparatively short period of sanatorium care, it may be that improvement under ideal conditions depends more upon the individual's resistance to the disease than upon the exact extent of his pulmonary lesions.

It is certainly known that many an early-stage case has steadily declined, in spite of the best care, while some apparently near the last gasp have rallied and even recovered a fair degree of health and activity. So far as immediate results in sanatoria are concerned (and they are, in my opinion, being consequent upon controlled treatment and known conditions, better gauges of this contention than uncertain after-histories, where even the actual physical state of the far-away patient is unknown) the last reports of the two principal sanatoria in New York State that receive both early and advanced cases show in a general way the usual outcome:

Table showing result of treatment in two principal sanatoria in cases staying at least three months.

	No.	Condition Upon Admission	Apparently Cured	Disease Arrested	Improved Only	Total Benefited	Unimproved or Failed
Adirondack Cottage	60	Incipient	20	23	14	57	3
Loomis	31	Incipient	23	4	3	30	1
Totals	91	Incipient	43	27	17	87 or 96%	4
Adirondack Cottage	97	Advanced	5	67	18	90	7
Loomis	91	Advanced	19	38	20	77	14
Totals	188	Advanced	24	105	38	167 or 89%	21

Here, aggregating, from the two institutions, the results obtained into improvements and failures we find that 96 per cent of the incipient cases improved and 89 per cent. of the advanced; surely the difference is not great enough to justify the abandonment of efforts to save the latter, yet upon the plea of doing the greatest good in the least amount of time, all the large sanatoria turn away thousands of indigent patients whose lives might be prolonged and even be made active again with a few months, or even years, of proper care and instruction.

All that the most vigorous of us are doing is to extend our lives for a little time; therefore, why should not the consumptive be encouraged to do likewise, especially if circumstances make it possible for him to live in comparative comfort?

Many of us have seen patients who were riddled with the disease, without apparently a square inch of perfect lung, in excellent physical condition and able to pursue a fairly active existence, and again others with involvement of barely the half of one lung who sank rapidly under the best of care. As has been said, lack of resistance, or of the ability to develop it, accounts best for the last mentioned, while the opposite, as exemplified in fibroid cases, explains the first, who, if they successfully run the gauntlet of the ever-threatening pus-germs, may survive indefinitely.

It is this last mentioned danger that engulfs so many of the advanced cases, for while the surgeon hesitates (as well he may) the abscesses poison and consume.

How remarkably and unexpectedly some cases improve under sanatorium regime was never brought to the writer's attention so forcibly as in his experience with the inmates of a small local sanatorium during the past year which, having no credit with those of the profession and laity nursing the old superstitions as regards the necessity of a special climate, was limited in patients to those well advanced cases for which I am begging sanatorium care.

The institution in question (a private one) only accommodating twenty-five, I have but the histories of twenty patients to present which were cared for therein during the past year. These, I think, will well repay perusal by any one who doubts the great constitutional resiliency of some of these patients when protected from everything except rest, good food and fresh air.

For brevity's sake and to offer nothing concerning antecedent conditions, often merely speculative, the institutional history is alone presented, and this without further comment.

MASTOIDITIS, COMPLICATED BY PURULENT LEPTOMENINGITIS, EPIDURAL ABSCESS, AND SINUS THROMBOSIS.*

By ALFRED BRAUN, M.D.,
NEW YORK.
ASSISTANT SURGEON, MANHATTAN EYE, EAR, AND THROAT HOSPITAL.

Cases of mastoiditis with intracranial complications are not very uncommon, yet the symptomatology of the various complications has not yet been so satisfactorily worked out, that case reports, especially when accompanied by autopsy findings, are without value. My excuse for reporting the following case is, in the first place, the fact that its clinical appearance and course did not conform to the picture usually seen in this disease, and the fact that it was possible to obtain a very complete autopsy.

Case.—Mrs. M. A., 37 years of age, was admitted to Dr. Berens' service, at the Manhattan Eye, Ear, and Throat Hospital, on July 2, 1908, complaining of a painful, discharging right ear, with some deafness and tinnitus, which had lasted about six weeks. Examination disclosed a moderate sized perforation in the anterior inferior quadrant of the right membrana tympani, through which exuded some seropurulent secretion. There was no tenderness over the mastoid process. Temperature and pulse were normal. Bichloride irrigations were ordered, to be used at home, every two hours, and the patient was advised to return to the clinic in a day or two.

She was not seen again until August 6, 1908, five weeks later. At this time she complained of intense headache over the right side of the head, which had lasted for three weeks. There was a boring pain in the right temporal region. She was somewhat excitable and begged to be taken into the hospital. Examination of the ear showed that the perforation in the drumhead had healed up, but the membrane was slightly pinkish, and thickened, and had not regained its normal luster. There was no tenderness whatever over the mastoid. She could bear very firm pressure over any portion of the mastoid process without wincing. Temperature, 100.2° F.; pulse, 84.

The patient was taken into the hospital. Examination of the eyes showed the pupils to be equal, and responsive to light and accommodation. There was a slight divergent strabismus which the patient says she has had all her life. There was a slight rotary nystagmus when she looked to the extreme right, left, up, or down. Ophthalmoscopic examination showed an old choroiditis in the right eye, with a slight blurring of the edges of the disc, and some fullness of the veins, *i. e.* a beginning optic neuritis. The left eye-ground was normal. The knee-jerks were possibly slightly increased and equal. She walked well. Her sense of position was good. There was no staggering or dizziness. No diminution of muscular power in any part of the body. No Kernig's sign. No Babinski sign. No rigidity of the neck. No areas of hyperesthesia or anesthesia. She answered questions rationally. Was somewhat excited. Blood examination showed 30,000 leucocytes. Differential count showed 92 per cent. of polynuclears. A lumbar puncture was made. About 5 c.c. of fluid was obtained. It was not under pressure, but came out drop by drop. The fluid was slightly turbid. Unfortunately, the specimen was mislaid in the laboratory before an examination was made.

*Reported at a meeting of the Bronx Medical Society, June, 1909.

During the night of August 6 the patient complained bitterly of headache. The next morning she became somewhat violent and attempted to jump out of bed. She was given morphine, gr. ¼, hypodermatically. She was fairly quiet during the day, and was more or less somnolent, with occasional rational periods. On the evening of August 7 she began to get periods of excitement again, and talked about committing suicide. She was given morphine, gr. 1/6, hypodermatically.

It was decided to do an exploratory operation the next day, but on the morning of August 8 her temperature rose to 105° F., her breathing took on a Cheyne-Stokes type, she became comatose, and died about half-past ten in the morning.

The post mortem, performed by Dr. Zabriskie, showed the following conditions:

The middle ear, the antrum, and mastoid cells were full of pus. The mastoid process was reduced to a mere shell of bone. There was a perforation, about one-third of an inch in diameter, through the tegmen tympani, leading to an abscess, in the middle fossa of the skull, containing about a drachm of thick greenish yellow pus, covered by an apparently intact dura. There was a thick purulent exudate covering the pia at the base of the brain, midbrain, and medulla, and extending upward on both sides, especially along the meningeal vessels, reaching somewhat higher on the right than on the left side. There were several clots in the right lateral and sigmoid sinuses.

The points of interest in the case are the following:

(1) The destruction of bone and presence of pus in the mastoid cells, antrum, and middle ear, without any mastoid tenderness and with scarcely any inflammatory signs in the membrana tympani. There were no perforation, redness, or bulging of the membrane. It was merely dull and thickened, and possibly a little pinkish.

(2) The presence of a purulent leptomeningitis, with so few of the cardinal signs. There was no rigidity of the neck, no Kernig's or Babinski's sign, no hyperesthesia or anesthesia, and no pupillary changes.

(3) The extension of the purulent process from the epidural abscess to the pia through an apparently normal intact dura.

156 East Sixty-first Street.

Treatment of Gastralgia.—E. Farroni says that the causes of gastralgia are numerous, and hence the treatment must vary with the cause. Among its causes are the various diseases, organic and functional, of the stomach, diseases of the liver, kidneys, appendix, lungs, and heart. Overeating may cause false gastralgia. All forms of malnutrition which result in intoxication may be added to the causes of gastralgia. Also all the exanthemata and infectious diseases. Hyperchlorhydria and achlorhydria may both be the cause of pain in the stomach. External topical applications in the form of heat, cataplasms, etc., and internal hot drinks are of value. The introduction of the sound to relieve distension when there is spasm of the cardia is of considerable value in gaseous distension of the stomach. Gastroenterostomy may be needed in some severe cases with anatomical changes in the stomach. Acetate of lead and nitrate of silver are useful in gastric ulcers which give severe pain. Alkalies are to be used in hyperacidity and acids in fermentations due to lack of acids. Antiseptics are useful in the fermentative cases. Sedatives may be necessary to relieve pain and relax spasm. Farroni therefore contends that we do not possess any specific treatment for gastralgia, and he says that it is necessary first to diagnose the cause of the pain and then to use such appropriate means of relief of the cause as the practitioner may be able to apply.—*Gazzetta Medica di Roma.*

THE BORSTAL SYSTEM FOR THE TREATMENT OF JUVENILE CRIMINALS.

ENGLAND, in fact, Great Britain generally, is very backward in so far as the intelligent humane treatment of criminals is concerned. In England punishment is intended to be deterrent, and the life of a prisoner is severe in the extreme. Doubts as to the advisability of excessively strict punishment are, however, beginning to invade the minds of British penal authorities, and it is openly stated by many that such punishment is not deterrent but merely debases and renders callous the men or women subjected to it and very frequently makes them hopeless criminals. Of course it goes without saying that these strictures apply with special force to youthful offenders, many of whom are absolutely made criminals by unnecessarily harsh treatment.

In consequence of the growing appreciation of these facts there has recently been introduced into England the so-called Borstal system which, from a perusal of its main features as set down in the *Lancet* of September 25, would appear to resemble somewhat closely the principles for treating criminals in vogue in the Elmira Reformatory in this State. The Borstal system is based on the principle that punishment in its legal sense, in so far as it is not a mere act of social vengeance, but purports to exercise a reformatory influence, ought to be as far as possible individualized; that, to vary the popular formula, it is more important to make the punishment fit the criminal than to make it fit the crime. This is to say, that the intelligent treatment of criminals is not to lump them together and treat them all with like severity, as has been the case up to the present time in England, but to treat different classes of criminals with different methods, and consequently the first step in devising a rational penal system is to differentiate the various classes of delinquents and to base treatment upon a careful study of the characteristics and natural history of each class.

The portion of the article in the *Lancet* which will appeal most forcibly to medical readers is that which considers the question of the origin and evolution of criminal instincts. The conclusion reached is that the criminal is not like the poet, who is born, not made, but is generally to a greater or lesser extent a victim of his environment. He cannot be assigned to a morbid or degenerate type. The stigmata of degeneracy, so-called, whether somatic or psychic, are rare in the professional criminal, nor does he suffer from the neuroses so commonly met with in the weak-minded offender. Further than this, the writer in our London contemporary states that there is reason to think that definite hereditary taint is not very common in the families of such delinquents. That the brain power of the criminal is more frequently than not above the average of the class from which he springs is notorious, and that he is, as a rule, physically inferior to members of the noncriminal population is again laid at the door of his environment. The final conclusion come to in this consideration is that the professional criminal is ordinarily an individual of fairly average aptitudes in whom the influence of an unfavorable milieu has given a wrong direction to normal tendencies. It is pointed out that acquisitiveness is a perfectly normal human tendency and that theft is merely this tendency carried in the wrong direction through lack of power of control. As the power of control is of slow development, and weak and imperfect during the period of adolescence, a certain predisposition to the crime of acquisitiveness may be looked upon as to some extent normal in the time of youth.

The principle, then, of the Borstal system and of the system in force in many of our reformatories, is to remove the individual at the critical time, that is, when he has exhibited criminal tendencies, from evil environment and to place him under wholesome influences. The system teaches him to use his brains in regular and interesting work; it provides him with a suitable diet and it steadies his unstable nervous system by physical exercise. In a few words, it is claimed for these methods that instead of, as under the former English scheme of penal treatment, really manufacturing criminals, they at least tend to render youths predisposed to bad habits, respectable members of the community. If this is true, reformatories for youthful offenders conducted on these lines are amply justified both from a moral and from a utilitarian standpoint. Perhaps, in England the system has been in practice scarcely sufficiently long to allow of an authoritative expression of opinion. In America, so far as we are aware, properly conducted youthful reformatories have yielded satisfactory results. It seems obvious that the endeavor to lead the young into right paths by precept and example and to nourish the mind and body with fitting food is a more rational proceeding than to brutalize and debase both by too severe punishment. It may be that the writer in the *Lancet* is inclined to ignore the influence of heredity, but that early environment plays a very important part in the moulding of character cannot be denied.

THE ACTION OF NITROGLYCERIN

THE nitrites have enjoyed a great deal of popularity in the treatment of heart disease ever since Lauder Brunton introduced them into therapeutics by advising their use in the spasm of the arteries accompanying attacks of angina pectoris. The *rationale* of their employment was based, of course, upon their ability to diminish arterial tension and thus re-

lieve a heart laboring against an abnormal resistance. The frequent relief met with in employing them in heart disease has, however, led many physicians to regard some of them, nitroglycerin especially, in the light of "cardiac stimulants," and has led to a quite unwarranted use of this drug in conditions of low pressure accompanying cardiac insufficiency. Moreover, extended observations have brought out still another point in the explanation of high blood pressure that accompanies many pathological conditions, whether caused primarily by circulatory, nervous, or renal changes. This symptom, namely, is being more and more looked upon as a conservative phenomenon that tends to supply with blood tissues which in the conditions of low blood pressure would not be thus supplied in the quantity necessary for carrying on their usual functions. Many practitioners, supported by this explanation, have therefore begun to doubt the supposed good effects of nitrites and have given up the use of them altogether in the treatment of circulatory disturbances.

Of course, the truth of the matter lies somewhere between these extremes of practice. Frequently high blood pressure, however conservative a phenomenon, may prove dangerous by itself, and then the effect of the nitrites in lowering it proves helpful, if not in the long run, at least for a short time while the dangers exist. On the other hand, judicious administration of digitalis or other true cardiac stimulants is beneficial in other cases in spite of high blood pressure, which may not be effective in distributing the blood properly or may interfere with the nutrition of the heart. These, in the main, are the conclusions of a recent student of nitroglycerin, L. F. Dmitrenko, writing in the *Zeitschrift für klinische Medizin,* Vol. XVIII, Nos. 5 and 6. In addition, however, he lays stress upon another point in the action of the drug, brought out by the simultaneous use of a Riva-Rocci blood pressure apparatus, registering the pressure of the brachial artery, and a Gaertner tonometer applied to the finger. In sixteen out of twenty-three cases Dmitrenko found that nitroglycerin, while causing a drop in blood pressure in the brachial artery, leads to a simultaneous rise of pressure in the smaller arterioles and capillaries of the finger. The mechanism of these changes remains to be shown, though probably increased blood supply to the small arterioles is in part, if not altogether, responsible for the rise of pressure in them. The fact, however, that nitroglycerin is not simply a pressure-lowering drug is clearly brought out. True, it leads to a dilatation of the blood-vessels; the changes in pressure, however, depend upon the conditions elsewhere at the time. With an efficient or a hypertrophied heart the blood pressure in the smaller radicles of the circulatory system may rise; with a weak or an exhausted heart the pressure may fall both in the larger arteries and in the smallest arterioles. In addition, the condition of the peripheral vessels, or of the "peripheral heart," as Dmitrenko terms them, their irritability, tone, and reserve strength, are the other factors active in the production of therapeutic effects.

Nitroglycerin, therefore, is neither a specific in all cases of circulatory disease accompanied by high blood pressure nor such a useless drug as some practitioners have of late tried to make it out. Its use requires simply the selection of suitable cases, for it affects not the essential cause of the abnormal phenomena but mere proximate results of mechanical conditions. With such judicious selection of cases its effects are evident and beneficial enough to warrant its retention in the group of important drugs in the treatment of circulatory disease.

DUODENAL ULCERS IN MARASMUS.

A FEW years ago the term marasmus was in general use as the name of a disease of infancy, and this diagnosis was considered quite sufficient to explain an illness or even the death of a child. As knowledge advanced, however, an increasing dissatisfaction with the word has arisen, and a general feeling is prevalent that the term is merely a cloak for ignorance; that there is always some definite disease or abnormality underlying these infantile atrophies, and that the physician should not be satisfied until he has done everything in his power to discover the underlying cause in each individual case. The result of this sentiment is an annual decrease in the number of cases diagnosed as marasmus, and a corresponding increase in the diagnosis of tuberculosis, hereditary syphilis, congenital heart disease, chronic colitis, improper feeding, and pylorospasm.

Nevertheless, when we have eliminated all of these from the old group of marasmus, there still remains a considerable number of cases, among the poor of our large cities a tragically large number, in which the children fail to thrive on any variety of food, and, for no cause that can be discovered, gradually waste away. In such cases we are forced to admit our ignorance and call them marasmus. In the *Archives of Pediatrics* for September, 1909, Helmholz of Chicago, writing from Germany, publishes a paper which may be an aid in explaining at least a few of these troublesome and mysterious cases. A few months ago the author reported nine cases of duodenal ulcer in young atrophic infants, and in the present article he adds seven more which he has seen in the clinics of Berlin and Breslau. These ulcers are easily overlooked, and are in fact found only by one who is looking for them with especial care. They may be acute or chronic, and their pathological anatomy closely resembles the gastric ulcer of the adult. In four of the seven cases there were during life no symptoms in any way suggesting an ulcer; in the other three there were hemorrhages.

The occurrence of duodenal ulcers in the infant, although considered as a great rarity, is not entirely unknown, as they have been reported as the cause of melena, as associated with pylorospasm, and as appearing apparently independently in children in fairly good health. The fact, however, that by careful search Helmholz has been able in the course of a few months, to find them in sixteen cases of unexplained wasting, lends a new interest to the lesion. If one man has found so many, it can hardly be considered a coincidence, and must mean that

duodenal ulcer is a far more common affection of infancy than has previously been believed.

These ulcers may be present even where there is no macroscopic evidence of blood in the stools, and this paper should lead the careful pediatrist to a systematic search for occult blood in the passages in every case of wasting of infancy. Such a procedure may add valuable information toward the elucidation of infantile atrophy. In such researches, however, it must not be forgotten that the mere finding of ulcers does not necessarily give us the cause of the wasting. The fallacy of the *post hoc, propter hoc* argument is especially evident in the present case, where the very condition of atrophy and poor tissue nutrition may easily be the cause of the erosions and the resulting ulcers in the duodenum. Then, too, granting that the ulcers cause the atrophy, we have yet to learn the reason for the ulcers. The subject demands further investigation.

Antituberculosis Campaign in New York.

The demands made recently on the Board of Estimate in New York, if acceded to, will insure a more vigorous antituberculosis campaign than ever before. A total of $432,000 is asked for the cure and prevention of tuberculosis. The Board of Health, Bellevue and Allied Hospitals, and the Board of Education have joined in the demand, which is based on a plan of action that involves the committee on tuberculosis of the Charity Organization Society and several other relief and philanthropic bodies. A central bureau on tuberculosis is projected for the Board of Health to centralize the work of tuberculosis clinics in the city, the medical inspectors and house-to-house visiting nurses, the hospitals, and relief associations. The Board of Health now asks for $109,000 additional appropriation to pay the salaries of 118 new inspectors who will be the force of the proposed central bureau. Here all reports of tuberculous cases will be received. The main purpose of the proposed central bureau is to protect the community from further contagion. It will try at once to mitigate this condition by keeping tab on all hospitals open to the tuberculous, and by helping in the distribution of patients to the best advantage and least peril to the city. The second step in the new tactics is the establishment of additional out-patient clinics under the Board of Health. Two new clinics are asked for. Patients attending these clinics will have the attention of visiting nurses, but only those whose home conditions are safe will be allowed to attend either the Board of Health or the other clinics in the city. The total appropriation asked for clinical purposes by the Board of Health is $112,000. At present the out-patient clinics of Bellevue and Allied Hospitals are crowded to double their capacity and $10,800 is asked to relieve the congestion. The Board of Health is asking an increase of $132,088 for the extension of the bureau of child hygiene. Finally, the Department of Education is asking for $3,400 for the instruction of the children recognized as tuberculous, who are now for the first time excluded from the public schools. This instruction, if the budget be granted, will be carried ahead even on the hospital ships where consumptive and otherwise tuberculous children are sent. The sum asked covers the salaries of two teachers now employed on hospital ships and three teachers to be employed on the roof of the Vanderbilt Clinic, the open air class of the Gouverneur and Beth Israel hospitals, and the open air class to be opened at the Greenwich Settlement. An additional $6,500 is asked to build and equip open air school rooms for anemic children.

The Accuracy of the Cammidge Test.

The introduction by Cammidge in 1904 of his urinary test for diseased conditions of the pancreas was hailed by both internists and abdominal surgeons the world over as one of the most important advances of the present generation in the knowledge of pancreatic disease. The test was repeated by others and generally accepted, the criticism tending more against its availability owing to its complicated technique than against its accuracy as a diagnostic sign. In the *Münchener medizinische Wochschrift* for September 14, 1909, however, Schumm and Hegler strike a note discordant to the general song of praise. Following Cammidge's technique, they examined the urine of seventy patients, whom they divided into two classes. The first class consists of twenty-seven cases in which the condition of the pancreas was ascertained either by operation or by autopsy. Of these, seven gave positive reactions. These cases were: one of fat necrosis, two of chronic cholecystitis, one of cancer of the uterus, two of cancer of the stomach, and one of ulcus ventriculi. The cases which gave negative Cammidge reactions, on the other hand, included a case of pancreatic cyst, two of operative injury to the pancreas, and one of pancreatic cancer. The second class of cases consisted of forty-three, both healthy and diseased, in which the condition of the pancreas was judged from clinical evidence only. In these the results were even more variable. Three healthy men gave positive reactions, and three others negative. One case of pneumonia was positive and three others negative. Frequently a case which, on one day gave a positive reaction, on a subsequent day was definitely negative. In short, the test appeared to be quite unreliable, and a positive reaction to be far from definite proof of pancreatic disease or a negative reaction reason for ruling out such a lesion. Whether these results will be confirmed by other investigators remains to be seen. In the meantime it must be remembered that, so far, this new test has stood the test of time and repetition fairly well, that it is a difficult procedure to carry out, and that the unsatisfactory results obtained by Schumm and Hegler may be the fault less of the method than of the investigators.

News of the Week.

Chicago's Mortality.—At the close of the first nine months of the current year the death record for Chicago stands at 23,485, equivalent to an annual rate of 14.12 for each thousand of the living population. For the corresponding period of last year the total deaths were 23,241, and the rate 14.75. This is a decided improvement in the death rate in favor of the current year, and if the deaths for the next three months are no higher than in the last quarter of 1908 the rate for the year 1909 will be 13.84 per 1,000 of population, the third lowest in the history of the city—the lower rates being 13.62 in 1904 and 13.67 in 1905. During the nine months of the current year there have been 51 fewer deaths from typhoid fever, 69 fewer from tuberculosis and 100 fewer from the acute intes-

tinal disorders, including "convulsions." As increased mortality is noted from heart diseases, Bright's disease, diphtheria, cancer, and violence. The three chief acute impure air diseases, pneumonia, bronchitis, and influenza, show a very slight increase—3,872 as against 3,840. The excess in the total actual deaths this year has been entirely among males, all over one year of age and all white. Deaths among males have increased 304, while among females there have been 60 fewer; the baby deaths have fallen off 466, while among those over one year of age there has been an increase of 710; the deaths among colored people show a reduction of 57, while among whites there has been an increase of 301.

The Illinois State Fair, held at Springfield recently, presented as one of its most important features an antituberculosis exhibit prepared by the State Board of Health. Beside the usual graphic representations now so well known in such exhibits and the statistics of tuberculosis in the State and country, there also appear copies of circular communications sent out by the Illinois State Federation of Labor to all trade unionists, showing how the federation and the board of health are cooperating in the fight against the disease.

To Prohibit Sale of Dangerous Hair Dyes.—A bill is being prepared under the direction of the Commissioners of the District of Columbia looking to the regulation or prohibition of the sale or use of dangerous dyes and hair washes. The attention of the Commissioners was called to the necessity of such legislation by a report from the health officer, W. C. Woodward. The report was based on cases occurring in the district in which women were poisoned through the use by hair dressers of a toxic substance in giving a dry shampoo.

Anterior Poliomyelitis in St. Paul.—The Board of Health of St. Paul and the medical profession of the city consider that the epidemic of infantile paralysis is practically over. In all 214 cases have been reported with 49 deaths.

Cholera in Vladivostok.—Since the outbreak of the present epidemic of Asiatic cholera in Vladivostok there have been, up to October 5, ninety-three cases and fifty deaths.

Cholera in Seoul.—Asiatic cholera is spreading rapidly in Seoul. Though great improvements have been made in the sanitation of the city by the Japanese during the last two years, it is still in an extremely filthy condition, and a widespread epidemic is feared. The disease is attacking all classes, the households of both the ex-emperor and the Japanese resident general having been invaded. Physicians of the Dai-Han Hospital, which Prince Ito recently opened, are doing tremendous work in disinfecting, and are ably seconded by medical missionaries.

A Case of Anthrax in Philadelphia.—A butcher in Philadelphia has died of anthrax incurred, it is believed, by being struck on the chin by a piece of flying bone.

The State Civil Service Commission will hold examinations on October 30, 1909, for the following positions: Medical Superintendent, State Tuberculosis Hospital, Ray Brook, $3,500; Woman Physician, State Hospitals and Institutions, usual salary, $1,000 and maintenance. Application should be filed on or before October 23. For information and application blanks address (postal card preferred) State Civil Service Commission, Albany, N. Y.

Clinic for Naval Surgeons.—During the visit of the foreign warships to New York for the Hudson-Fulton celebration the visiting naval surgeons were invited to a special surgical clinic at the Roosevelt Hospital. The clinic was under the direction of Dr. George E. Brewer.

Naturopath Arrested.—A man who called himself a naturopath and styled himself professor was arrested recently in New York for the illegal practice of medicine. This is this individual's third arrest for the same offense.

Prehistoric Skeleton Found.—The discovery is announced of a fossilized human skeleton in the Department of Dordogne in Southwestern France. Accredited scientists declare it to be 20,000 years old. The area in which the fossil was found, where Dr. Capitan, professor at the College of France, has been carrying on researches for three years, is about four miles from Bugue. The skeleton, which is absolutely intact and surrounded by the fossilized bones of animals, was imbedded in the middle of a quaternary formation. Calculations as to its age are concurred in by four well-known geologists.

Hospital Ship Nearly Ready.—Surgeon-General P. M. Rixey of the navy has officially notified Secretary Meyer that the United States ship *Solace*, which is being fitted out at the Charlestown Navy Yard as a hospital ship, will soon be ready for service. Surgeon-General Rixey has recommended also that the *Solace* be placed in commission as soon as possible in accordance with the existing regulations. This recommendation will have the effect of reviving the discussion as to whether a surgeon or a line officer shall command the hospital ship. Under the present naval regulations a medical officer must be assigned to command the hospital ship.

Charitable Bequest.—By the will of the late Mrs. Emily A. Gore of Owego, N. Y., the sum of $30,000 is left in trust, and on the death of the present beneficiaries will revert to the St. Rose Free Home of New York City.

The McPherson Hospital Association was organized recently in McPherson, Kan. The association will let contracts for the construction of a new modern hospital. The lot has been purchased and work will be begun soon on the hospital. The latter will cost about $14,000, and when completed will have a capacity of thirty beds. Among the board of directors appear the names of Dr. A. Engberg and Dr. J. C. Hall.

Resignation of Hospital Staff.—The entire visiting staff of the Elliot Hospital of Manchester, N. H., with the exception of one member, resigned recently. No specific statement as to the reason for the resignations has been made other than dissatisfaction with the present matron of the institution. As in the disagreement the trustees took the part of the matron the medical staff resigned, each man to leave as soon as the patients now under his care are discharged. The members of the medical staff have agreed to stand together to prevent a compromise.

Addition to St. Louis Hospital.—Ground was broken recently for the new wing to the City Hospital of St. Louis. This addition is to cost $800,000, and is expected to be completed within two years.

College of Physicians of Philadelphia.—The new building, just completed at a cost of more than $300,000, will be formally dedicated on November

10. It contains in addition to the library, having a capacity of 300,000 volumes, large and small halls and rooms for lecture and meeting places, as well as the Samuel D. Gross Library and the Mütter Museum.

The American Public Health Association will hold its thirty-seventh annual meeting at Richmond, Va., October 19 to 22, 1909. Dr. Gardner T. Swarts of Providence, R. I., is president of the association, Dr. Charles O. Probst of Cleveland, O., secretary, and Dr. E. C. Levy, Chief Health Officer of Richmond, chairman of the committee on local arrangements.

New York and New England Association of Railway Surgeons will hold its nineteenth annual meeting at the Academy of Medicine, New York City, on November 16-17, 1909. A symposium will be presented on the "Causes of Railway Accidents Individualized." Dr. J. M. Wainwright of Scranton, Pa., is president of the association, and Dr. George Chaffee, 338 Forty-seventh street, Brooklyn, is corresponding secretary.

The National Association of Military Surgeons met at Washington recently and elected the following officers: *President*, Col. Joseph K. Weaver of the National Guard of Pennsylvania; *Secretary*, Major Charles Lynch, U. S. A., and *Assistant Secretary*, Surgeon William H. Bell, U. S. N. The next meeting will be held at Richmond.

The Northern Berkshire Medical Association meeting at Stanford, Mass., September 28, 1909, elected the following officers for the ensuing year: *President*, Dr. Harry L. Holmes of Adams; *Vice-President*, Dr. Philip S. Potter of North Adams; *Secretary and Treasurer*, Dr. L. V. Jones of North Adams.

The Tri-County Medical Society, composed of the counties of Barbour, Randolph, and Tucker of West Virginia, at a meeting held at Davis, W. Va., recently elected the following officers for the coming year: *President*, Dr. L. N. Harris of Mill Creek; *Vice-Presidents*, Dr. A. P. Butt of Davis and Dr. E. M. Hamilton of Belington; *Censor*, Dr. John W. Bosworth of Philippi; *Secretary and Treasurer*, Dr. T. J. McBee of Elkins.

Obituary Notes.—Dr. Pasquale De Cunto of Denver, Col., died in New York, October 6, 1909, aged 43 years. He was a graduate of the University of Naples, in 1898, and immediately after his graduation he moved to Denver. In recognition of his charity toward his fellow countrymen in the West, Dr. De Cunto was made a Chevalier of the Order of the Crown of Italy by the late King Victor Emmanuel. He was a member of the Denver County and Colorado State Medical Societies.

Dr. Leonard W. Arnold of Florence, Ala., died in Memphis, Tenn., on September 25, 1909. Dr. Arnold was a graduate of the medical department of the Vanderbilt University, in 1882, and was a member of the Lauderdale County Medical Society and the Medical Association of the State of Alabama.

Dr. John F. Irvin of Des Moines, Ia., died at his home, September 25, 1909, at the age of 90 years. Dr. Irwin had practised medicine for over sixty years, forty-one of them in Iowa.

Dr. Lewis E. Powell of Waynesboro, Ga., died suddenly at his home, September 20, 1909. He was a graduate of the Atlanta College of Physicians and Surgeons in 1899.

HOLMES MEMORIAL MEETING OF THE MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

A special meeting of this society was held on the evening of October 9, in celebration of the one hundredth birthday of Oliver Wendell Holmes. The President of the Society, Dr. H. Seymour Houghton, after welcoming the guests, showed why it was appropriate that the Society should commemorate the work of Dr. Holmes. He said that it was fitting that the meeting should be in the hands of those who had known Dr. Holmes, and that he would, therefore, vacate the chair in favor of Dr. A. Jacobi. Dr. A. Jacobi, in accepting the Chair, said that it was not with any sense of mourning over the death of Holmes that they met, for he had died full of years and achievements, but with a joyful reminiscence of his birth which began a career of manifold study, intellectual growth, useful practice, and teaching of medicine, in part new and epoch making, and instructive and entertaining writing beyond what was usually meant by those adjectives. He was a rare combination of the scientist and the poet. The multitude of his gifts of heart and mind was startling and pleasing and warming.

Personal Reminiscences of Oliver Wendell Holmes.—Dr. Maurice H. Richardson of Boston, a student and assistant of Dr. Holmes during the later years of his teaching, described Dr. Holmes as he had seen him in the class room and demonstrator's room. He had to teach a subject repulsive to some, difficult for all, and he had to teach it to the class at an hour when the students were jaded and unfit to be taught anything. In order to make head against these odds he did his utmost to inject a sprightly manner and let no opportunity for a jest escape him. He gave his imagination full sway in comparisons, often charming and always quaint. None but Holmes could have compared the microscopical sweat gland to a fairy's intestine. He likened the mesentery to the shirt front of a preceding generation from which a short line of attachment expanded into yards of complicated folds. Dr. Holmes would introduce his lecture with some bright remark, anecdote, or witticism which served to enlighten the wearied students; he would then plunge at once into his subject. Dr. Richardson said that his method of exciting interest at the beginning and keeping up that interest surpassed that of any speaker, medical or lay, that he had ever heard. Dr. Holmes' enthusiasm and influence put the study of anatomy on a higher plane than that which it had occupied before or after his day. He presented the dry facts of anatomy in such a way that it was impossible ever to forget them. He called to his aid everything that would vividly illustrate his point, the association of ideas, humor, anecdotes, or mnemonics. One point of which Dr. Holmes availed himself offered greater possibilities to-day than in his time, and that was the bringing out of the applications of anatomy. The dissections prepared for him were really works of art, and would be looked upon as remarkable at the present time. His assistants took this unusual care because of the great appreciation that Dr. Holmes showed for their work. They were sure that if they did well they would receive much more praise than they deserved. Many of Dr. Holmes' writings seemed to be prophetic. In regard to what the physician learned from the surgeon he wrote in 1851: "The physician has learned a great deal from the surgeon, who is naturally in ad-

vance of him, because he has a better opportunity of seeing the effects of his remedies." Again, in comparing bedside with laboratory teaching: "I am in little danger of underrating anatomy or physiology; but, as each of these branches splits up into specialties, any one of which may take up a lifetime, I would have them taught with a certain judgment and reserve, so that they shall not crowd out the immediately practical branches." Dr. Richardson related many anecdotes illustrating the wit and resources of this unusual man as a teacher.

Dr. Holmes' Achievements as a Physician.—Dr. Edward O. Otis of Boston, who had been a pupil of Dr. Holmes in the old Harvard Medical School, expressed his fear that the achievements of Dr. Holmes as an author were in danger of causing us to forget the contributions he made to medicine. Dr. Holmes was first a physician and secondly a literary man. In his literary works one was constantly meeting with anatomical, physiological, psychological, or pathological allusions. One felt that it was the doctor who was writing and not merely the literary man. He was a constant deep and independent thinker on medical problems. He recognized and persistently opposed the inordinate use of drugs and insistently advocated the study of causes of disease and the supreme importance of depending upon Nature and Nature's remedies for their cure. He remarked in stating "the case on the side of Nature," that "if every specific were to fail utterly, if the cinchona trees all died out, and the arsenic mines were destroyed, and the sulphur regions were burned up, if every drug from the vegetable, animal, and mineral kingdom were to disappear from the market, a body of enlightened men, organized as a distinct profession, would be required just as much as now, whose province would be to guard against the causes of disease, to eliminate them if possible, to order all the conditions of the patient so as to favor the efforts of the system to right itself, and to give those predictions which only experience can warrant, and which relieve the exaggerated fears of sufferers and their friends, or warn them in season of impending danger." Again he says: "Is not the function of the medical profession regarded as preventive, higher, better, happier than the function of the medical and surgical profession regarded as curative?" Dr. Holmes was an incomparable medical interpreter and critic; he might have been an original investigator had he been less of a literary man. He gave the profession new and clearer ideas upon the great principles of medical practice. His message was ever to the practitioner of medicine, emphasizing its art as distinguished from science. His essay on "The Contagiousness of Puerperal Fever" constituted his greatest claim to recognition as an achiever in medicine. This was a notable contribution at the time it was written and there was something chivalrous in the writing of it. Next in value and importance was the essay on "Currents and Counter-Currents." His essay on "Direct Exploration" was a careful and thorough exposition of the value and use of the methods of direct exploration and their employment in the detection of thoracic disease and was in some respects superior to the unnecessarily complicated modern guides upon the subject. Dr. Otis referred to other medical essays of Holmes and especially commended his excellent literary style to the writer on medical subjects, as much medical work was lacking in this respect.

Holmes—Author, Poet, and Man.—Dr. William Hanna Thomson called attention to the fact that the present year had been remarkable for its centenaries of great men and that the one thing in common that led to the remembrance of these men who had risen above their fellows was that they had all been benefactors of the race. As the world grew better and wiser this title to Fame would more and more take precedence. If so the future would particularly sound abroad the names of the great members of the medical profession. The beneficent aims of their profession took in all mankind. Therefore it was fitting that we should celebrate the birth one hundred years ago of Oliver Wendell Holmes. As an author he could be judged by his inimitable "Autocrat." His lucid, vigorous, terse style was the result of his study of the classics, especially Greek. It was vexing to hear so many weaklings in our day decrying the time spent hitherto in our colleges on the musty old classics. The classics qualified a man for everything, including business, and afforded a wonderful mental gymnastics which trained thought as nothing else did. The man in the medical profession without a preliminary college training rarely arose afterwards above a certain mediocre level. If Oliver Wendell Holmes had not taken the training of that grand old intellectual gymnasium, Harvard, he never would have been the Autocrat. It was difficult to describe the poetry of Holmes. Underneath his wit there was an undertone of deep feeling. There were certain qualities of heart that endeared this man to all who came in contact with him.

Mr. Richard Watson Gilder related a reminiscence of Holmes and recited the following poem, which he said was written for a birthday while the Doctor was still living:

God bless the day; but He hath blest
(And all the grateful world doth know it)
That happy day when, in the West,
Was born the wise and witty poet.

The poet who first to science sought
And to the Merry Muses after,
Who learned what in no school is taught,
The secret of men's tears and laughter.

Be it, O Time, a weary while
Ere, in the land where spirits greet us,
A shade will say (with Shakespeare's smile)
"Here comes the Autocrat to meet us!"

Correspondence.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

SCHORSTEIN LECTURESHIP—ABSCESS OF THE BRAIN ASSOCIATED WITH LUNG DISEASES—PLAGUE, RATS, AND FLEAS—HEALTH OF THE NAVY—HEAT STROKE.

London, September 24, 1909.

The proposal to establish a lectureship at the London Hospital in memory of Dr. Gustave Schorstein, whose death took place on November 16, 1906, has been duly carried out. He was a distinguished student of the University of London and of Oxford, where he took the M.B. and B.Ch. in 1889. Two years later he became a member of the College of Physicians, of which he was elected a Fellow in 1897. At the London Hospital he had served the offices of house physician, house surgeon, and registrar, became assistant physician in 1894, and a full physician in 1905. In the college he lectured on public health and on pathology. He was also on the staff of the Brompton Hospital for Consumption, the Children's Hospital, the Ophthalmic Hospital, and in his time filled other important clinical appointments. His industry, clear pathological views, and great experience secured him a very high regard among his colleagues. On his pre-

mature decease his friends and admirers resolved to establish a memorial and raised above £1,000 for the purpose. Arrangements having been completed, it has been announced that the Schorstein lectures on clinical medicine will this year be given by Professor Osler of Oxford. In the meantime what may be regarded as the introductory lecture is the work of the late physician himself, viz., his "Thesis" for the degree of M.D. at Oxford, which consisted of a careful essay on "Abscess of the Brain in Association with Pulmonary Disease," in which he detailed all the cases at the Brompton Hospital during 1882-1904 (twenty-two years), and at the London Hospital during 1894-1904 (ten years). There were seventeen cases in the former and only two in the latter. The most frequent pulmonary antecedent of cerebral abscess was shown by collating cases from original records to be bronchiectasis, and in this disease such abscess is the second most frequent cause of death. This does not agree with the common idea that empyema is the main pulmonary cause of cerebral abscess. Gangrene of the lung is not often associated with cerebral abscess and did not occur once in Dr. Schorstein's experience, and of recorded cases he found only six, and of these he thought four would probably be regarded now as bronchiectasis. Tuberculosis of the lung is very rarely associated with cerebral abscess; so is acute pneumonia. Böttcher's case of lung abscess associated with cerebral abscess has so often been referred to that it could not be passed over in such an essay as this, especially as he stated that he found lung pigment in the cerebral abscess, though the means of distinguishing this are uncertain and the observation has not been confirmed.

The only recorded case of emphysema and bronchitis associated with abscess of the brain must be regarded as a concidence. Cases of idiopathic abscess in the brain are sometimes recorded and it is possible some pulmonary disease may have been a causal antecedent just as suppuration elsewhere, though undetected, may have determined secondary abscess. But to say, as some have done, that the brain has a special predisposition to suppuration is pathologically inaccurate, for, as Schorstein observed, it is well recognized that in general pyemia, from any cause whatever, the brain is by no means the organ most frequently affected. But though not specially liable to suppuration, it is possible that the brain may not be so fully protected by antitoxins as some other organs, and so cannot resist so effectually the septic emboli from pulmonary suppuration. This is a mere surmise, as Dr. Schorstein himself remarked. But if these cerebral abscesses are embolic, as seems certain, we cannot doubt that similar emboli are carried to other organs also and do not necessarily produce abscesses in them. Many other interesting points are treated in the "Thesis," clinical and pathological observations abound in the nineteen cases, all of which are reprinted at length in the *Lancet* of the 18th, but unfortuntaely in very small type.

A consular report from the Azores, issued this week, shows that the outbreak of plague which began in the Island of Terceira and soon spread to Fayal, was fought with commendable energy by the local authorities. Several of the municipal bodies offered rewards for rats' tails, and in this way endeavored to exterminate the rodents. A medical commission was sent from Lisbon to assist the local authorities as to sanitary measures and advise with the resident doctors on the cure of the cases.

It is not often we hear a good word for the rat, but Mr. Richard Kearton interposed one in a lecture before the Ornithological Society on "Wild Birds That Can Be Observed Near London." He exhibited numerous photographs of shy birds he had taken in various places, and among them one of a number of rats feeding on oatmeal which he had spread for them taking care not to touch it with the hand on account of their keen sense of smell and suspicion. Then he said that the rat was the cleanest animal he knew. It was surmised in early times that the rat had something to do with the spread of plague, but no satisfactory explanation was forthcoming until the rat flea was pronounced to be the carrier. Even admitting this, there is room for differences of opinion. Some of these were expressed at the Congress at Buda, for a correspondent sends word that there were two interesting papers which gave occasion for discussion. Professor Kitasato said there were five varieties of fleas on rats—the pulex cheopis being the most important in this respect: but it did not spread the disease by its bite, but by its feces. It was certain that plague spread from rat to rat, but further proof was needed that it spread from rat to man. Still, rat destruction was the most important method of controlling epidemics. Among means of doing this cats should be kept, but chiefly as preventives. This has been done in India, but if the cats are too well fed they become indifferent ratters. Other means of exterminating rats were mentioned at the meeting. One member had obtained virulent bacilli in large numbers from the intestines of the pulex cheopis, and crushed flea smeared on gelatin would yield free culture. Another member thought there were varieties of plague bacilli which would have to be differentiated and probably other bacilli more or less resembling them.

One more note as to the rat and flea theory. On Friday the question was asked in the House of Commons whether the Indian Government adhered to this theory, and the answer was in the affirmative. The connection between plague and rats was held to be well established and destruction of rats continued to hold a prominent place among the preventive measures adopted in India. In reply to a further question, the Under Secretary said he had not seen a statement in the public press that the theory had been disproved.

Another question in the House was answered by the Home Secretary signifying that he approved the regulations of the College of Surgeons for the admission of women, and he believed all formalities would be concluded in time to admit women to the examinations in January next.

The Home Secretary, replying to another inquiry as to compelling patent medicine vendors to print on every package the ingredients contained, intimated that this question and the form of stamp affixed was under consideration and he was inclined to think it important enough to be the subject of a select committee next session.

The Blue Book of the Medical Department of the Navy for the year 1908 is just issued, and shows a continuous improvement in the health of the fleet. Not only the case, invaliding, and death ratios were lower, but the average loss of service for each man had dropped from 11.28 to 10.36 days. The decrease of invaliding was 2.91 per 1,000, compared with the average of the previous five years. There was a decrease of 0.54 on the death rate average. The causation of heat stroke is the subject of an interesting report by Staff Surgeon Oswald Rees, who says the negro has an advantage over the white in the sun, and also in the stokehold, for the lesser diathermacy of his dark skin is an advantage in the sunshine, and in the stokehold it radiates heat better. He adds that it is curious that workers in the bunkers of ships are not more liable to heat stroke than those firing the furnaces, for the bunkers are often much hotter than the stokeholds, and the air in them almost motionless. He offers as an explanation that the stoker is at once covered with a thick layer of fine coal dust, which will radiate the heat much faster than the uncovered body. The heated engine room, with absence of air circulation, would seem to present ideal conditions to produce heat stroke, but there is a saving condition in the absence of severe muscular exercise as long as the engines are running, the attention then amounting practically to carrying around the oil can. But in the stokehold the conditions are the reverse. The actual throwing of the coal on the fire must be done quickly to avoid the cooling action of the air and consequent loss of steam. So the cleaning of the fire is no leisurely performance. Staff Surgeon Rees thinks the most satisfactory method of treatment is by iced baths.

OUR LETTER FROM THE PHILIPPINES

(From Our Regular Correspondent.)

SPECIFIC TREATMENT OF TUBERCULOSIS—NEW SEWER SYSTEM IN MANILA—PERSONALS.

MANILA, P. I., August 30, 1909.

THE regular monthly meeting of the Manila Medical Society was held at the Philippine Medical School on Monday evening, August 3, at 8.30.

A paper by Captain and Assistant Surgeon E. R. Whitmore and Dr Waldemar Christensen, entitled "Specific Treatment in a Comparative Series of Tuberculosis Cases," was read by the latter. The treatment was begun at the Bilibid Hospital (which is the State Prison of the Philippines) on January 14, and carried out according to the plan outlined in the report of Surgeon Wright, United States Navy, viz., intramuscu-

lar injections of mercury succinimide in .013-gram doses to toleration. Twenty prisoners were placed upon this treatment, and the report shows that on June 30 of this number three, or 15 per cent., had been returned to duty, 35 per cent. died, and the remainder, or 50 per cent., are still under treatment without any marked improvement having taken place in their condition. In one of the cases that was returned to duty it is interesting to note that the weight was ten pounds less than at the time he was placed under treatment; so that the cure would, no doubt, be questioned by many authorities. It may also be worthy of notice to state that the percentage of cures is smaller than that occurring among prisoners who are given the ordinary open air and symptomatic form of treatment.

The installation of the new sewer system for the city of Manila ranks second only to the new water system; it is one of the most costly of permanent sanitary improvements that has been completed since American occupation, and ranks easily among the best installations in the Orient. It also furnishes a most striking example of the different method of sewage disposal in Manila as compared with other large Eastern cities. Here the removal of night soil is a source of great expense to the Government, the installation of the system having cost $1,650,000, and the annual operation charge will be at least $75,000, almost half of which can be credited to night soil; while in cities like Hongkong or Tokyo there was no charge for installation, and there is an annual revenue of about $37,500 and $1,500,000, respectively.

The ordinances which will prescribe the rules and regulations which are to govern the questions as to who, when, and how connections are to be made have been receiving most careful consideration since April. Every effort is being made to have the system universally used without causing actual hardship. It is obvious that there will be many instances in which a person may have sufficient means to construct a house which would comfortably meet his needs, and which would cost perhaps $150; but in order to install the necessary sanitary fixtures which could be safely connected with the new sewer system an additional outlay of a similar, or even greater, amount would be necessary. This is a condition which obviously must be met.

The sewers range in size from 20 centimeters to 1.75 meters, and the slopes are sufficient to warrant a velocity of not less than 65 centimeters per second flowing one-half full. The minimum depth is 1.5 meters, and the maximum depth is 5.4 meters.

Five substations are required to give the system the flow mentioned above, and are located as follows: Ermita, with a capacity of 5,000,000 gallons for 24 hours; Santa Cruz, with a capacity of 12,000,000 gallons for 24 hours; Quiapo, with a capacity of 5,000,000 gallons for 24 hours; Malate, with a capacity of 2,000,000 gallons for 24 hours; and Paco, with a capacity of 800,000 gallons for 24 hours.

These pump the water to the main pumping station, which is located on the beach in the lower part of Tondo, the latter having a capacity of 25,000,000 gallons for 24 hours. The main station has a lift of approximately 8.8 meters, and discharges into the bay through a 1.05-meter cast iron force main laid 3.05 meters below the bed of the bay at a point approximately 1½ kilometers from the shore. This pipe terminates in a vertical position, which was done for the purpose of making the discharge take place above the bottom of the bay. This outlet end is encased in a huge block of cement masonry, which rests upon a timber platform supported by a group of piles.

Branches or outlet pipes have been provided at intervals of 12 meters throughout practically the entire sewer system. The system will be ventilated by omitting the vent pipe and continuing the soil pipe and vent stack of each house connection full size through and above the roof. Flush tanks with suitable connections to the water system supply have been constructed at the ends of the primary lateral sewers for the purpose of keeping them clean and in a satisfactory condition. These tanks have been built to hold about 1,320 liters of water each, and are provided with gates and handles for operation by hand. This feature is unique and has been introduced for the first time in Manila.

The pumping plant consists of centrifugal pumps driven by electric motors, and are supposed to be automatic, the rise and fall of the sewage in the sewer starting or stopping the pumps as occasion may require.

Some idea of the magnitude of the contract may be gathered from the fact that the excavation alone represented 260,100 cubic meters and the iron pipe used weighed 2,180 metric tons and measured 2½ kilometers. Of this there were 1.9 kilometers of 1.05 meter pipe used for the outfall and sewer in the bay and the balance of from 0.2 of a meter to 0.6 of a meter. The concrete used in this construction was represented by 30,600 cubic meters, and in this work over 50,000 barrels of Green Island cement were utilized. All the main sewer was constructed of concrete, as were over 900 manholes and 265 flush tanks for flushing the entire system. The length of the main sewer is approximately 12.87 kilometers, built in egg shape.

Over 1,630 cubic meters of brick masonry were laid in the manholes, in which over 1,200,000 bricks were used. The terra cotta pipe laid covers in all over 68 kilometers varying from 0.2 to 0.6 meter. For bracing the excavations alone the company utilized over 1,000,000 feet of lumber, which gives some idea of the extensive operations under way at one time throughout the city in order to make headway, meet every requirement of the contract, and at the same time not impede traffic in the city streets.

Passed Assistant Surgeon Ebersole of the Public Health and Marine Hospital Service, who has been on duty in the Philippines during the past three years as quarantine officer at different periods at Manila, Mariveles, and Cebu, has completed his tour of service, and has been directed, at the expiration of two months' leave of absence, to report at San Francisco.

Passed Assistant Surgeon McKeon of the Public Health and Marine Hospital Service, who was temporarily detailed to relieve Dr. Hough at Hongkong, has returned to Manila and resumed his duties of quarantine boarding officer at Manila.

Progress of Medical Science.

Boston Medical and Surgical Journal, September 30, 1909.

Nasal and Nasopharyngeal Conditions as Causative Factors in Middle Ear Disease.—G. A. Leland says that all these conditions act by preventing the proper ventilation of the middle-ear cavity. A consideration of the question concerns (1) the structure of the Eustachian tube, its muscles and surroundings, and their physiological movements, and these are all described in full. (2) The influence of normal respiration (respiratory movements of the membrana tympani). That respiratory movements do occur in the latter structure has been demonstrated experimentally by more than one observer. Hence a rational treatment demands continuous free nasal respiration in order to maintain proper circulation of the blood and lymph. The time to cure chronic catarrhal otitis media is before the initial earache has occurred or any exudate has formed which causes drum depression and probably subsequent adhesions in the middle ear. Hence parents must not permit the earaches of their children to go unattended. The middle ear never forgets the attack of pain. Stress is also laid on the necessity of keeping clean the fossæ of Rosenmüller. The author refers to hospital statistics of 127 cases of scarlet fever, of which 43 were free from adenoids. Of the 84 with adenoids 72 were without aural complications, past or present. Of the 12 with adenoids and aural complications, 5 had the adenoids generally distributed over the nasopharynx, while in the remaining 7 they were confined to the fossæ of Rosenmüller.

The Diagnosis of Phthisis and Its Association with Certain Simulating Diseases.—C. Floyd and W. W. Barker discuss certain frequently neglected points in the diagnosis of phthisis, taking up the general symptoms, the accelerated pulse, and the great value of sputum examination in diagnosis. The diagnosis of most cases must be made before the sputum is positive. In many instances if the whole sputum were examined the percentage of positive cases would be greatly increased. With the disintegration of the sputum by sodium hydrate and the use of the centrifugalized sediment, a far larger number of bacilli might be demonstrated on the first examination. The matter of variation in physical signs receives full consideration. The use of tuberculin as a diagnostic measure is of more value in determining the presence or absence of the process than in its localization. With the subcutaneous test, however, the presence of a local reaction may indicate the seat of the disease, and the character of the response will aid us in deciding whether the lesion is quiet or active. Of the conditions which simulate phthisis mention is made of valvular cardiac disease, Bright's disease, diabetes, bronchial asthma, and chronic bronchitis. Acute endocarditis is as baffling as any. Various nervous conditions, as neuras-

thenia, dyspepsia, and even simple debility, often puzzle us for a long time. Certain influenza cases often simulate tuberculosis. The authors make a plea for the exercise of infinite pains and judgment in the early detection and treatment of pulmonary tuberculosis.

Distinction Between the Psychoneuroses Not Always Necessary.—G. L. Walton says that, after eliminating from the cases presenting nervous symptoms without known organic basis those whose features are sufficiently marked to justify their classification under hysteria, hypochondria, or manic-depressive insanity, there remains a large, perhaps a larger, number whose symptoms are not distinctive. The effort to place each of these cases under one or the other category is unsatisfactory. The efforts of the textbooks to distinguish between the minor forms of these conditions are confusing, the symptoms given being practically identical. To apply the term "neurasthenia" to all these cases is neither logical nor satisfactory, since this term implies a condition distinct from the other psychoneuroses, to say nothing of the fact that the term implies the asthenic condition which is far from constant. In the present state of our knowledge and study of these conditions, the most satisfactory solution seems to be to place under the diagnosis hysteria, hypochrondria, and manic-depressive insanity such cases only as have dominant features characteristic of these disorders, and to group the remainder under the general term "psychoneurosis" until definitely diagnostic features appear.

New York Medical Journal, October 2, 1909.

Persistence of the Gonococcus in the Prostate. This topic is considered at length by G. A. De Santos Saxe, who speaks of the method of obtaining prostatic secretion, technique of staining, frequency of prostatitis as a complication of gonorrhea, relation of this complication to posterior urethritis, occurrence of the gonococcus in the prostatic secretion, value of the bacteriotaxis by means of incubation, persistence of the gonococcus in the prostate, mixed infection in gonorrheal prostatitis, relation of clinical data and microscopical appearances, and finally summarizes as follows: (1) Thorough irrigation of the urethra before massaging the prostate is essential in order to exclude contamination of the prostatic secretion by pus and bacteria from the urethra. (2) Injections of 15 drops of a 1 per cent. solution of silver nitrate into the urethra 24 to 48 hours before prostatic massage sometimes reveal gonococci when other means have failed. (3) A double stain of eosin and methylene blue in pure methyl alcohol, after the manner of the well known blood stains, is excellent in the morphological study of prostatic smears. Gram's stain is essential, but is misleading, unless properly applied. (4) Cultures, while desirable, are often unsuccessful, owing to the capricious character of the gonococcus. Negative cultures are not conclusive. (5) Of 150 cases of chronic gonorrheal infection, from six months to eighteen years' duration, 69 per cent. showed prostatitis. The older the infection, the more frequent was the prostatitis. (6) Of the 108 cases of prostatitis studied, 31, or 28.7 per cent., showed gonococci in the prostatic secretion. The older the infection the less probable was the finding of gonococci in the prostate. After three years, gonococci were found rarely, even after most persistent efforts. Many and thorough examinations are needed before we can be at all certain that the gonococcus is absent from the prostate. (7) Mixed infection occurred in 80 per cent. of the cases studied. The gonococcus was found in only 3 cases of 168, and all 3 were cases of less than one year's duration. The older the case the more frequent was the mixed infection. Staphylococci occurred in 74 per cent., bacilli in 28 per cent., Gram positive diplococci in 10 per cent., and streptococci in 7.6 per cent. of cases with mixed infection. (9) The value of microscopical examinations of prostatic secretion was shown by the fact that palpatory signs were absent in 38 cases (35 per cent.), while 13 cases (12 per cent.) showed absolutely clear urine, although the smears showed prostatic infection. (10) Gonorrheal prostatitis is curable by proper treatment in the great majority of cases. (11) Consent to marriage should not be given until all methods of examination have been exhausted, and until the possibility of a postmarital infection is practically excluded, in the present state of our knowledge.

Treatment of Locomotor Ataxia by a Modification of the Reeducational Exercises.—F. V. Fruchthandler says that the most important objection to the practice of this form of treatment is the fact that it necessitates the use of various paraphernalia, so that it could be carried out only in special institutions. He has therefore devised a system of muscular movements which by means of a diagram (given in the paper) can be executed by anyone under any circumstances. They are adapted to bed patients as well as to those who are able to be up and about, and are applied to both extremities and to the eyes. If during a seance there should be a pulse of over 120, remaining over 100 after five minutes, rapid breathing, profuse sweating, sudden weakness, fascinating pains, or stumbling, the exercises should be stopped immediately and the patient rest for fully one-half hour. Directions are also given for cases with vesical paresis, hypotonia, and drop feet. Regarding these exercises the author says that results from their use have been very satisfactory. Under their employment he says that the ataxia will in most of the cases be cured permanently, and in a minority the alleviation of this symptom will be very marked. The length of time necessary for a course of treatment varies in each individual case, but as a general statement it may be said that it takes from two to nine months to effect a cure from the mildest to the most severe type of ataxia. Of course, says the author, there are cases that it would be wise to leave alone. He refers here to those patients that are in the beginning of their disease, where the ataxia has not reached its acme. These cases naturally do not improve because the ataxia is in a rapidly progressive stage. Another set of cases where treatment is contraindicated are those that have a combination of tabes and paresis. In cases of combined sclerosis, where the posterior and lateral columns are affected, no good results have been obtained.

Postoperative Suppression of Urine.—A. B. Cléborne refers to the various etiological theories of this condition, but expresses no preferences for any one of them. He says that further work on healthy animals is necessary to settle this question. We have no definite knowledge as to the nature of the exact pathological changes present. Consequently our present therapy is very vague. It includes hot packs, hot air baths, saline infusions and irrigations, intravenous injection of salines, cupping, dusling the bowel, etc. Sometimes these do good and at other times are entirely useless. The author finds the use of sparteine sulphate hypodermically in doses of one or two grains every four to six hours the most reliable plan, though he admits that it is purely empirical.

Operation for Brain Tumor.—H. Augustus S. P. Kramer gives a full description of the operation in one case. A tumor of the dura was found, and on account of its large size and the shock experienced by the patient its removal was postponed for three days. It was found that the growth sprang entirely from the dura, and was not adherent to the brain. It was readily removed, and weighed 125 grams. The patient died on the fifth day; no autopsy; wound was found clean. Certain variations in the two radial pulses during the surgical period were noted, and were referred to cerebral vasomotor influences. The authors add that in the three days which elapsed between the two operations there was considerable protrusion of the tumor through the opening in the skull, even though the opening proved to be too small to permit the delivery of the tumor at the second operation. Is it not possible that if we had waited a month instead of three days this large tumor might have been gradually delivered by the pressure from behind? The brain would have been allowed gradually to expand, so that the tumor might have become a mass directly beneath the scalp, that might easily have been removed without any considerable shock. Thus we might have saved our patient.

Journal of the American Medical Association, October 2, 1909.

Mental Disorders in Women.—W. P. Manton, after a review of the history of former work on pelvic disorders in the insane, summarizes the results obtained in the last few decades. We have learned, he says, that while the mind may exert a remarkable influence over the bodily functions the reverse is also true, the mental state of the viscera aggravating the existing mental maladies and even causing insanity. The frequency with which abdominal-pelvic disorders exist in insane women has been determined, about 80 per cent. of them being abnormal in this respect. The frequency, or rather the infrequency, of postoperative insanity has been determined. And eclampsia has been shown to be an almost negligible factor in the etiology, though childbed is responsible, according to Kraepelin, for 6.8 per cent. of insanity in women. The delusions and hallucinations of the insane have also been shown often to depend on intraabdominal or pelvic lesions. As regards the curability of insanity by operations on the pelvic organs, he admits the results are not as favorable

as some enthusiasts have made out, but whether a cure is effected or not the relief and cure of bodily suffering is imperative in these cases and may be beneficial, though far short of curative, as regards the mental condition.

Drainage in Gynecology.—H. G. Wetherill says there is a growing disposition to simplify practice in the matter of drainage and irrigation in obstetrical and gynecological operations. The use of the solutions of antiseptic drugs, especially poisonous ones, is steadily losing in favor, and the principles governing the best modern practice would seem to be as follows: "Never irrigate if it be possible to avoid it through gentle wiping or sponging. Avoid poisonous and irritating solutions, as they are both dangerous and disappointing. In the main, use irrigation for its mechanical effect in flushing out débris and always at low pressure." The prevailing opinion at present as to drainage is also strongly in contrast to that of a few years back. The majority of the best surgeons of to-day limit irrigation and drainage to certain specific indications, chief of which are rupture or leakage from some hollow viscus or from some abscess. In many cases pus accumulation of long standing and tubal origin can be broken down and turned out through an abdominal incision without irrigation or drainage, and certain localized peritoneal infections can be treated similarly. Often in such cases the peritoneum will take care of itself though the wound in the abdominal wall may suffer serious infection which, if unprovided for by a superficial drain down to the peritoneum may cause anxiety. Whenever intraperitoneal drainage is really necessary in gynecological surgery, it is better to make it down hill, *i.e.* through the vaginal vault, thus avoiding the risk of hernia and also on account of other advantages. The routine employment of uterine douches is still practised by some physicians, although the weight of authority is decidedly against it, and Wetherill speaks severely of the way some physicians have of clinging to ancient ways. Intrauterine drainage is, under some circumstances, important, but it should be open and free and capable of carrying away thick fluids and adapted for flushing. Such a drain he devised years ago and illustrates it in his paper. One of the most dangerous features of the ordinary intrauterine douche as practised is the danger of infection of the uterine cavity from the infected vaginal, cervical, and vulvar regions, and the patient is to be congratulated if she escapes. Similar retrograde infections of the bladder are of common occurrence. The advantages of an irrigating and draining device that can be placed once, and only once, with due precautions against infection are evident. He mentions the use of his device and its success in uterine and bladder infections.

Traumatic Insanity.—A. S. Brush discusses the traumatic insanities, of which, excluding hysteria, he recognizes three types: psychic trauma causing traumatic hyperchondria, and physical trauma, acute primary traumatic insanity, organic dementia, or idiocy, and imbecility. He holds that the so-called traumatic neurosis or hypochondria may be defined as a fixed delusion on the part of the patient that he has sustained some severe and permanent injury from traumatism, and this is often complicated by hysteria or neurasthenia or both. It may arise from an exaggeration by the patient of the injury, from an error of diagnosis on the part of his physician, or from his exaggeration of the difficulty, or from litigation for damages, and usually more than one of the causes are combined. The prognosis of the condition is of marked medicolegal importance, and the effect of an early and correct diagnosis is equally marked. The effect of litigation in prolonging the psychosis was very evident in the author's cases. Acute primary traumatic insanity is one in which injury is the only recognized cause, and the symptoms of the insanity must be continuous with the symptoms of the injury or connected with them by a definite train of brain symptoms. Insanity is not a common result of head injury, and Brush finds, with Meyer, that it occurs most frequently in those with neuropathic heredity or suffering from alcohol or syphilis. The clinical picture and course of a case of this form of insanity are diagnostic of a severe cerebral contusion. The invasion is rapid and when dementia follows this psychosis it is always the result of epilepsy, arteriosclerosis, or alcoholism, in the author's experience. Recovery may occur, in from two months to two years as he has observed, but death or dementia are frequent results. Organic dementia following the acute primary disease is, of course, permanent. Brush does not credit the ordinary forms of insanity as being primarily due to the traumatism, and, if they occur, it is only the development or exaggeration of a previously existing condition or tendency. He has never seen a case of general paresis from this cause, and regards it most probable that it is an error of diagnosis or an aggravation of an existing condition.

Lake Michigan Water.—W. A. Evans describes the conditions in Lake Michigan as regards pollution from sewage by the large centers of population around it and the means that are being taken to remedy this state of affairs. Twenty miles away from shore it is pure, containing eight bacteria to the cubic centimeter, but the present conditions near the large towns make the shore waters dangerous for drinking purposes. The currents are inconstant and largely influenced by the wind, shore contour, etc., and the intakes being in water less than fifty feet deep are within the zone of peril. A flow of seven miles in Lake Michigan is not sufficient for the purification of a massive amount of sewage, though the greater dilution than in streams is more effective, and a forty-mile requirement of river flow is not equaled by a one mile of lake flow on account of the lesser amount of saprophytic bacteria in the lake water. No town should place its water intakes within one mile of the sewer outfall of a town of 2,000 inhabitants and the distance should increase with the population. Dumping should not be allowed in water less than sixty feet deep, and government navigation regulations should keep shipping at a certain distance from water intakes at all times. Properly controlled, he says, Lake Michigan water will always be safe for drinking purposes, but under present conditions no town is justified in using Lake Michigan water from a point nearer shore than one mile, and large cities emptying their raw sewage into the lake should not take their water any nearer any sewer outfall than ten miles. Evans thinks that the national government should take up and do the work on the chain of lakes which the states and cities on Lake Michigan are trying to do.

Protection of Water Supplies.—H. B. Wood points out that municipalities are not the only factors accountable for the pollution of public water supplies, and that more attention should be given to the influence of small villages and individual homes and factories on stream contamination. Cities produce the most pollution, but the bacterial contamination is apt to be relatively less from a city than is the case with a small town, with its numerous cesspools. The danger from rural contamination has been amply illustrated by such facts as the Ithaca epidemic, and a water pipe laid through a polluted town may become sufficiently disjointed to permit infection, as occurred at Baraboo, Wis. Public wells becoming infected through ground seams have caused epidemics of typhoid. Manufacturing plants are not a danger from their sewage alone, but their liquid wastes, when discharged into water courses, are undoubtedly a damage, not only to individuals using the water, but are a detriment to other mills and are destructive to fish. Even when the discharge of chemical waste is disinfectant or purifying, as in the case of chlorinated lime from paper mills, etc., emptied into a sewage infected stream, it is apt to be so much in excess that a poisoning of the water results. The scarcity of food fish is largely due to stream pollution, not only by sewage, but by factory wastes, containing, as they often do, poisonous chemicals. They also affect the life along the shores and sometimes make it impossible to live near streams or to water live stock from them. Realty values decrease markedly along polluted streams. Since factory pollution is easily visible, it should be reported by the inspectors and should be under the control of the health officers. Too many factory toilets are built directly over streams. No offensive factory discharge should be allowed to go at once into streams without purification. If possible, the waste should be converted into industrial profit, as is done in some instances. The efficacy of sand filters has been shown to be not much below experimental results. Rural contamination of streams should receive more attention than is being given to it, though some still insist that there is no danger if the stream is not used for domestic supply. Such streams are rarities.

The Lancet, September 25, 1909.

Juvenile Myxedema.—D. A. Thomson reports one case, the patient being a girl of 18 years, 40 inches high, and weighing 58 pounds. Her general appearance was that of a child of 6 years. She developed normally until the sixth year of age, when she seemed to cease growing and become fatter. The symptoms of the condition made the diagnosis lie between juvenile myxedema, infantilism, and chondrodystrophia fetalis. Thyroid treatment was immediately begun, two grains of desiccated gland being given for fourteen days and then doubled. No improvement fol-

lowed. Iodothyrine was then given, the dose running up from 2 to 15 grains daily. On this régime she began to grow in height and diminish in weight. On the maximum quantity she began to show signs of overdosage, and finally she was given 1 grain daily. After that she gained no more in height nor lost in weight, but her mental condition improved greatly, and from being a silent member of her family she became an active, intelligent child. Menstruation had not appeared when the case was reported.

Congenital Dislocation of the Hip Joint. Ultimate Results of the Manipulative Operation and Note on a New Open Operation for Relapsed Cases.—J. J. Clarke refers to his previous writings on this subject. In his first series of twelve cases eight were cured and one improved, while three failed. In one case in which he had twice done the Lorenz manipulation and a relapse had followed each time, owing to a deficiency in the ilium and ischium, which form the upper and posterior borders of the acetabulum, he devised and carried out successfully the following operation, which consists in exposing the joint from behind, making a small opening in the lowest limit of the posterior aspect of the capsule, and introducing an elevator to raise the periosteum and with it the cotyloid ligament for a short distance at the upper and posterior borders of the acetabulum. Next three stout silk stitches are passed in turn through the periosteum thus raised into the joint cavity under the cotyloid ligament, out of the capsule again and through a fold of the capsule, then once more through the capsule near its femoral attachment, where the two ends are tied. These stitches remove the overdistention of the back of the capsule and hold the cotyloid ligament over the outer part of the head of the femur. The limb is put up in plaster as after the manipulative operation, which must always have preceded this open operation. The postoperative course was quite like that after the manipulative operation, and there was no evidence of intraarticular adhesions being present when the plaster was removed. The proceeding differs from the open operation of both Hoffa and Lorenz, which involved an excavation of the acetabulum, and when necessary a reshaping of the femoral head through a free opening in the joint capsule.

Arteriovenous Anastomosis for Gangrene.—The patient of D. J. Armour and E. A. Smith was an old man of 69 years with evident thrombosis in the right foot and leg. He was persuaded to undergo an operation for arteriovenous anastomosis, with a view to reversing the circulation in the limb and so attempting to stop the onset of gangrene by conveying arterial blood through the venous channels. The upper end of the femoral artery was sutured to the lower end of the femoral vein, both vessels having been severed in the area between the middle of Scarpa's triangle to the middle of Hunter's canal. The quill suture method was employed. On the fourth day after the operation a line of demarcation began to form at the level of the upper and middle thirds of the leg on the outside, and the lower and middle thirds on the inside. Fourteen days after the operation the leg was amputated by a circular incision a hand's breadth above the knee joint. In two weeks the patient left the hospital on crutches. The authors claim that this is the first application of the quill suture method in human surgery. The authors say that the catgut used in such an operation should be capable of resisting absorption for not less than a month. Although examination of the amputated extremity showed considerable thrombosis in the veins below the level of amputation, it would appear that there must have been some conveyance of blood downwards on the part of those veins which were not completely thrombosed, on account of the increased warmth and fullness of the veins over the front of the knee after the anastomosis and before amputation, and also on account of the marked distention of the vein between its junction with the artery and its ligature in the stump after the amputation. This distention coincided with an increase in strength and blood pressure on the part of the patient, and with the closure of the main outlets for blood from that portion of vein between the suture line and the ligature. Had this distention occurred sooner, the valves of the popliteal vein would have been made thereby incompetent, and their obstruction to the vein taking on the function of an artery done away with.

British Medical Journal, September 25, 1909.

Calomel in Asthma.—C. B. Tivy recommends in asthma a combination of antispasmodics with calomel, giving from one-half to two grains. Other cathartics do not seem to act as promptly. In the author's experience relief comes before catharsis takes place.

A Simple Method of Treating Certain Fractures of the Mandible.—H. P. Pickerell says that for various reasons it may be desirable in cases in which the fracture is at the angle of the mandible or in the region of the last molar tooth to cut down from the outside and wire or screw the fragments in apposition; the only treatment then consists in fixing the mandible to the maxilla in its normal position and maintaining it so until union has occurred. This fixation may be attempted by means of a four-tailed bandage or some modification of the same, which usually fails to immobilize the jaw, and is, moreover, exceedingly uncomfortable for the patient. Interdental splints are practically of no use in such cases, as they fail to secure the smaller fragment and cause too much separation between the upper and lower jaws, which separation may possibly be permanent. The following method has none of the above disadvantages and has the merit of being so extremely simple that no specialized skill is required in its application, and it can be carried out in a very short time and without any special appliances. It consists simply in fixing the lower to the upper jaw by means of horizontal ligatures passing round the crevices of two or more teeth in each jaw, the ligatures being securely connected by a third vertical ligature. Diagrams in the paper make the author's technique perfectly clear. There is no difficulty in feeding these cases or in keeping the mouth clean. The vertical wire ligature may be left on for a month, after which it may be removed and passive movements allowed; it may be replaced by silk ligatures, as being easier to apply. A vertical ligature should be continued until the sixth week, especially during the time or times the patient sleeps, in order to prevent yawning, as the latter does far more harm than even a slight amount of mastication.

Compressed Air Illness Cured by Recompression.—E. R. Thomas relates the history of a diver in the British navy who was working in nearly a hundred feet of water. In such circumstances it is customary to raise him a certain number of feet toward the surface, wait a little while, and then repeat the process until he is taken out. Soon after this man was taken from the water he was found lying down and pale with violent nystagmus. Though intensely dizzy he was able to answer questions and was clear in his mind. He was transferred to another vessel on which there was a recompression chamber, into which compressed air was introduced, and immediately began to revive. Restoration of the air toward the normal pressure brought on a return of his symptoms, and an increase of pressure again brought relief. In about two hours he was removed from the chamber, given some slight stimulant and hot broth, and the next day was all right. In this particular instance, owing to rough weather at the surface, it had been necessary to remove him from the water somewhat more quickly than the tabulated schedule governing such matters allowed. Recompression in such cases is often unsuccessful, owing, says the author, to the fact that the volume of the air bubbles liberated in the blood and tissues is too great to be successfully dealt with. There seems every reason to believe that the more the dissolved air has been gotten rid of in consequence of the precautions taken in decompression, the greater will be the probability of recompression promptly relieving any symptoms even after a considerable time after their appearance. Another fact shown is the necessity of extreme caution to be exercised in decompression after recompression and the consequent desirability of being able to keep the patient comfortable during this tedious process.

Berliner klinische Wochenschrift, September 6, 1909.

Method of Obtaining Hemochromogen Crystals.—Angelo de Dominicis describes a new and simple method of procuring crystals of hemochromogen. The dried blood is pulverized on a slide, and a drop of pyridin added to it. Over this a drop of a saturated solution of hydrazine sulphate is placed, and the slide held in the flame until definite bubbles appear and a purple color is produced. The preparation may be preserved in balsam. Crystals may also be produced without heating by adding, instead of the hydrazine sulphate, a reagent consisting of caustic soda and hydrazine sulphate. The first method, however, gives a brighter field, and the crystals are more isolated and of sharper outlines. The method is simple and sure. The author has obtained the crystals from blood nineteen years old, which would not give hemin crystals.

Münchener medizinische Wochenschrift, September 14, 1909.

The Permeability of the Kidneys to Bacteria.—Rolly investigated the question as to whether the healthy kidney is permeable to bacteria or only the diseased organ. He

examined the urine of nineteen cases of typhoid fever. In seven there was no sign of albumin, in twelve there was a trace. In three of the seven without albumin typhoid bacilli were found in the urine. Of the twelve with albumin the typhoid bacillus occurred in eight. He then carried out some animal experiments, thirty-four on rabbits and four on dogs. Permanent catheters were used. *Staphylococcus citreus*, *Bacillus pyocyaneus*, and *Bacillus kiliensi* were used as organisms which would not injure the kidney. Emulsions were injected into the jugular vein. The results of the experiments, which are reported at length, was that bacteria injected into the blood would appear in the urine in from three to thirty minutes as regularly in apparently normal animals as in those with kidney lesions.

Fulguration in Treatment of Cancer.—Schultz describes the good results reported by other authors in the use of the Keating-Hart method of treating cancer, namely, the direct application of the electric spark. He reports thirteen cases of his own in which the method was used with a voltage of 250,000 to 300,000, the spark being applied from a distance of 2 to 4 centimeters. None of the cases received lasting benefit. The pain was not relieved. Quick epitheliation often gave one hopes for results, but these were disappointed. Decrease in the size of the glands was not seen. In two cases the fulguration appeared to stimulate to increased activity in growth of the tumor. He was unable to see that the fulguration was of value in a single case in the treatment of cancer. As to other instruments and methods he cannot speak, but is very skeptical.

Deutsche medizinische Wochenschrift, September 9 and 16, 1909.

Tubercle Bacilli in the Blood.—Schnitter discusses the history of efforts to obtain the tubercle bacillus from the circulating blood of phthisis cases. The earlier authors all emphasized the difficulty in obtaining the organisms from this blood. The author says that there are three possible methods. Direct cultures from the blood are very difficult to obtain, and uncertain. Inoculation of guinea pigs is by far the most accurate method, but this requires from two to four weeks' time, and so is of little value in diagnosis. Stäubli had devised a method of obtaining the organisms directly. This consisted in treating the blood with a 3 per cent. acetic acid solution. This destroyed the red cells without injuring the tubercle bacilli. This solution was then centrifugalized and the precipitates spread and examined. Schnitter used this method modified only by using 1 to 2 c.c. of blood and examined a series of tuberculous cases. Of eight cases in the first stage of the disease all were negative. Of nine cases in the secondary stage two, or 22 per cent., were positive. Of seven cases of the third stage eight, or 47 per cent., were positive, while of four cases of tuberculosis of other organs than the lungs two, or 50 per cent., showed the organisms in the blood.

Nervous and Psychic Symptoms of Arteriosclerosis.—Cramer, in a lengthy discussion of this subject, first divides the nervous symptoms into general and local. The characteristic general symptoms are dizziness, headache, and reduction of mentality. The dizziness is the symptom which usually alarms the patient. The character of the headache varies. It may be a boring pain, a dull headache, or an acute knife-like pain after exercise or any dietary indiscretion. The diagnosis is evident when on a chronic headache is superimposed a sudden attack of dizziness. This may be a true turning dizziness and may cause the patient to fall. It must be differentiated from neurasthenia, late epilepsy, and internal ear disease. The attacks increase in frequency. The reduction in mentality is usually present. Speech and memory are affected. Emotional attacks are common. The patients are inclined to tears on slight provocation. Depression and pessimism are frequent symptoms. The whole individuality may change. Marked irritability may be found. The effect on sleep is variable; sometimes the patients are sleepless, sometimes soporific. Tolerance for alcohol is often greatly reduced, one glass of wine making the patient intoxicated. An important local symptom is slowing of the speech and uncertainty in pronunciation. There are usually changes in the pupillary reaction. These become sluggish and are reduced both for light and accommodation. Only in advanced cases is there a complete loss of reflex. Involvement of the facial nerve may occur early, and cause a partial paralysis. Paralysis of the cerebral nerves are rare. The reflexes are usually increased. The patients often complain of paresthesias and pains in the extremities. Slight thromboses may cause sudden apoplectic symptoms which later clear up. These vary according to the elevation and size of the hemorrhage. The differential diagnosis from neurasthenia may usually be made by careful search for symptoms of an organic nature. It is much less injurious to consider a neurasthenic as a sclerotic than to mistake a sclerotic for a neurasthenic. The psychic symptoms are increasing weakness of mental power, mild or severe depression, and euphoria or exaltation, occasionally the paranoic symptom complex. The intellectual degeneration is gradual and usually begins as a loss of memory. Ethical defects and moral perversions are common in previously normal men. This, added to increased irritability, makes the patient difficult to live with. The most common psychic result of arteriosclerosis is a state of depression. This is difficult to differentiate from true melancholia. The patients are usually more stupid, and careful examination usually shows some sign of organic nerve disease. The cases of exaltation are at times mistaken for paranoia. There may be delusions of persecutions sometimes based on auditory hallucinations. The occurrence of apoplectic attacks clears up the picture. The course of the sclerotic cases is slower than in paresis; the prodromals are more drawn out. The Wassermann reaction is positive in the blood serum of both arteriosclerotics secondary to syphilis and paretics, but in the cerebrospinal fluid both this reaction and Nonne's are practically specific for tabes and paresis, except in cases of cerebral syphilis, which can be ruled out easily, especially by therapeutic tests. A knowledge of the clinical pictures of nervous or psychic arteriosclerotic symptoms is not of academic interest only, but is practically important, as an early diagnosis and proper treatment in certain cases causes a halt in the progress of the disease and prevents social and material injury to the patient and his relatives.

Neurasthenia.—Jendrassik discusses this disease and concludes that it is a single definite disease, the symptoms of which may vary greatly in individual cases. There is, however, no definite symptom group characteristic of neurasthenia; it is more the combination of changing symptoms which characterizes it. The basis of neurasthenia is a hereditary increased irritability of the nervous elements of definite portions of the brain. There is no brain weakness. On the contrary the brains of neurasthenics are more active than those of the healthy. The increased irritability causes a restlessness, even an ability for greater activity. The neurasthenic cannot be separated from the normal by any sharp line of demarkation. The mild cases border on the normal and the severe ones verge into paranoia.

Malignant Adenoma of the Liver.—Ribbert concludes that malignant adenoma of the liver made up of galliferous liver cells is a definite form of tumor, and should not be mistaken for the primary liver carcinoma arising from the epithelium of the bile passages. It begins in a primary nodule, from which the process spreads to the neighboring organ either by direct extension along the vessels or by metastasis through the portal vein. The primary nodule arises either from liver cells which have been pinched off by a cirrhotic process or possibly from a previous hyperplasia.

Duodenal Ulcer and Its Treatment.—Einhorn discusses this subject. He says that duodenal ulcer is more frequent in men than in women. Until recently a positive diagnosis could be made only by operation. Since the introduction of the thread test it can be diagnosed with some degree of certainty. He reports six cases. In all six there was marked hyperchlorhydria, and in some continuous hypersecretion. Pain occurred two to three hours after meals. There were alternate periods of suffering and euphoria. Bleeding (hematemesis or melena) was present in two patients. There was usually constipation, but a tendency to diarrhea appeared in two cases. Point tenderness occurred in all. The treatment is at first medical, regulation of diet, and general hygiene. Olive oil, two tablespoonfuls morning and night, is of value. In severe cases a strict ulcer cure must be carried out: bed, rectal feeding, and large doses of bismuth. In very severe cases gastroenterostomy is of especial value. The condition is more dangerous than gastric ulcer, and operation must be advised earlier.

Kala-azar in Sicily.—Umberto Gabbi has observed several adult cases of kala-azar in Sicily, hence this rare disease is not confined to children. The symptoms are fever with chills and sweating. This is accompanied by gastrointestinal disturbances, poor appetite, and diarrhea or dysentery and an increasing asthenia. The disease is to be differentiated from malaria and infantile splenic leukemia.—*Il Policlinico.*

Book Reviews.

Severest Anemias. Their Infective Nature, Diagnosis and Treatment. By William Hunter, M.D., Edin., Fellow of the Royal College of Physicians of London; Physician and Lecturer on General Pathology and Morbid Anatomy, Charing Cross Hospital; Physician to the London Fever Hospital. Vol. I, with historical schemes, charts, and plates. London: MacMillan & Co., Limited, 1909.

The author has long held very original views on the subject of the severer forms of anemia, and in this work he brings forward his well known theory of the etiology that the disease is a chronic infection. He believes that we should abandon the use of the term "pernicious anemia" so generally employed in Europe and America, preferring the term "Addisonian anemia," because Addison described cases before Biermer published his first paper on the subject. While others, notably Herter, have attempted to show that this Addisonian anemia or progressive pernicious anemia, as it is generally known, may possibly be due to a chronic intestinal infection with bacteria whose toxic products are hemolytic, Hunter considers the site of the infection as largely oral. Neither of these views is, however, widely held, though it is well known that in pernicious anemia there is an active blood destruction going on, and that the poison of the parasite *Bothriocephalus latus* may induce an anemia with a similar blood morphology and clinical picture. The book does not add much to the writer's previous publications on the subject, and certainly does not settle the pathogenesis of this very obscure disease, though an excellent series of photomicrographs show many of the changes in the gastrointestinal tract thought to be characteristic. In the opinion of the reviewer, the author does not strengthen his position by his citation of published cases. Many of these are evidently not of the type of anemia which he is describing or have been so incompletely studied as to be of no value. A very full and well-classified bibliography, chiefly of English and American writers, adds greatly to the value of the book as a complete historical study.

Atlas und Grundriss der Röntgendiagnostik in der Innern Medizin. Bearbeitet von Prof. Dr. Carl Beck, New York; Prof. Dr. Ludolph Brauer, Marburg; Dr. Franz M. Groedel, Bad Nauheim; Dr. Georg Fedor Haenisch, Hamburg; Prof. Dr. Friedrich Jamin, Erlangen; Dr. Alban Kohler, Wiesbaden; Prof. Dr. Paul Krause, Bonn; Prof. Dr. Gustav Spiess, Frankfurt a/M; Prof. Dr. med. et phil. Anton Steyrer, Berlin. Herausgegeben von Dr. Franz M. Groedel, Bad-Nauheim. Mit 297 Abbildungen auf 12 photographischen und 44 autotypischen Tafeln und mit 114 Textabbildungen. München: J. F. Lehmann's Verlag, 1909.

In adding this seventh volume to Lehmann's medizinische Atlanten, Franz Groedel has rendered a signal service to the profession. On first examination the book would seem one prepared exclusively for the Röntgen specialist, but closer study shows it destined for all to whose work precise diagnosis is essential. The manner in which the book is written is such that it will prove invaluable for those whose line of effort embraces such organs and conditions as are perceptible by the *x*-ray. As illustration hereof, mention of the heads of the chapters alone will serve: 1. "Special Röntgen Technique for the Internist," wherein Dr. Franz M. Groedel details and illustrates the use of the instruments necessary for general internal diagnostic purposes. 2. Prof. Spiess describes the Röntgen examination of the upper respiratory passages. 3. Groedel discusses the Röntgen pictures obtainable from the normal thorax. 4. Prof. Jamin illustrates the diaphragm and respiration. 5. Prof. Krause analyzes the *x*-ray appearances of the trachea in health and disease. 6. The Röntgen diagnosis of mediastinal and pulmonary tumors is presented by Prof. Krause, who 7 also details the *x*-ray diagnosis of pulmonary tuberculosis. 8. Prof. Steyrer describes the technique of the Röntgen diagnosis of pneumonia and of the other pulmonary diseases. 9. Prof. Brauer studies and describes the diseases of the pleura as revealed by the *x*-ray; as he also does o the diseases of the pericardium. 10. Groedel enters deeply into the Röntgen diagnosis of cardiac affections. 11. Prof. Krause shows the changes produced by disease of the blood-vessels. 12. Groedel explicitly demonstrates how clearly the *x*-ray exposes gastrointestinal diseases. 13. Prof. Beck of New York, with habitual thoroughness, exhibits all the details of Röntgen studies of the liver and gall-bladder. 14. X-ray descriptions of the uropoietic system are very well made by Haenisch, and 15 Dr. A. Kohler illustrates the diseases of the skeleton. These fifteen articles, each one replete with a wealth of information, are followed by a list of the literature up to January, 1909, containing about 1,500 titles. These are classified in twenty seven divisions, that make rapid reference to any department of Rontgenology easy. The brilliant work terminates with photographic and autotypic plates, whose clearness and fidelity serve well to illustrate the text, wherewith they are in keeping as to utility for study and practice.

Nouveau Formulaire Magistral. De M. le Professeur A. Bouchardat. Trente-quatrieme édition. Par le Dr. G. Bouchardat, Membre de l'Academie de Médecine, Professeur a l'Ecole Supérieure de Pharmacie de Paris, Professeur Agrege a la Faculte de Médecine de Paris. Paris: Felix Alcan, Editeur. 1909.

When a book has gone through thirty-three editions it may be safely said that it has established its existence. This new edition has been thoroughly revised and brought in line with the new codex of 1908. A number of the newer remedies receive notice. A few pages are devoted to serum therapy and to organotherapy. The French must have (or have had) good eyes, for we have never seen a book better calculated to ruin one's eyesight than the volume before us.

The Sexual Disabilities of Man and Their Treatment. By Arthur Cooper, Consulting Surgeon to the Westminster General Dispensary; formerly House Surgeon to the Male Lock Hospital, London. New York: Paul B. Hoeber, 1909.

In this small volume there is ample discussion of sterility and impotence as found in man. The author handles the subject in a masterly way; his methods are scientific, his language is clear and dignified; he further shows his skill by omitting all unnecessary details. Thus, while cases are referred to, there are no "sexual histories" or other pornographic details, and for this the sane reader will be duly thankful. The book is a model of its kind, and will be of real service to physicians.

Naval Hygiene. By James D. Gatewood, Medical Inspector, United States Navy. Philadelphia: P. Blakiston's Son & Co., 1909.

It is a real pleasure to review this book, not only because of its intrinsic merit, but of the evidence it furnishes of that general spirit of admirable professional zeal which animates the medical department of our navy under its present efficient Surgeon General. The book stands in a class by itself, inasmuch as it is the first complete guide which we have for safeguarding the health of the sailor. It contains a vast amount of information to this end, the very newness of much of which to the ordinary reader emphasizes the fact that preventive medicine on board ship is very much of a specialty with which even those familiar with health measures on shore must necessarily be largely in ignorance. With the rapid development of the navy the changing conditions of naval life are constantly modifying naval sanitary problems and imposing new and increasing obligations upon the medical officers.

The book consists of eight chapters, treating of the following general subjects: Naval vital statistics; the air without and within the ship; the light without and within the ship; the ship's water supply and drainage; the navy's food; the navy's clothing; disinfection on the ship; naval recruiting. These chapters are all long, and if one were inclined to be critical with such a generally excellent book it might be suggested that shorter chapters, covering a necessarily less heterogeneous mass of subjects, would have been preferable. Dr. Gatewood's facilities for the work as assistant in the office of the Surgeon General of the navy and as instructor in hygiene at the Naval Medical School have rendered him peculiarly fitted for the preparation of this book, and his text embodies much valuable matter hitherto buried in official reports, as well as the results of much necessarily personal and original investigation. The scope of the book is wisely limited to service on board ship, for, although sailors and marines are frequently called on for shore duty, the special problems then presented are analogous to those of the land forces, and are covered by the several books on military hygiene which are already in existence. The limitations of the book in question are therefore such as commend it chiefly to such medical men as "go down to the sea in ships," whether on vessels of war or of the merchant marine.

By his arduous pioneer work Dr. Gatewood has done a service of future inestimable value to the navy, since his book will undoubtedly long serve as the basis upon which subsequent editions or modifications can without great difficulty be based on the hygienic adaptation of naval life to the meeting of changing times, conditions, and methods

Society Reports.

AMERICAN PEDIATRIC SOCIETY.

Twenty-first Annual Meeting, Held in Lenox, Mass., May 27, 28, and 29, 1909.

(Special Report to the MEDICAL RECORD.)

THE PRESIDENT, DR. CHARLES P. PUTNAM OF BOSTON, IN THE CHAIR.

President's Address.—Dr. CHARLES P. PUTNAM of Boston said that his remarks were in line with the paper to be read by Dr. Rotch. He urged pediatrists to take up a share of the work of public institutions for children in their own communities. Public institutions for children were to a great extent great hospitals for chronic patients. These children, whether juvenile offenders, truants, dependents, or neglected children, should not be taken on the whole as healthy and normal. Physicians were well fitted both by their experience and training for this work. Twelve years ago three unpaid boards of seven persons each were created by the General Court of Massachusetts to take charge of insane, paupers, and children's institutions in the city of Boston. To the board in charge of children's institutions four separate divisions and several classes of children were handed over, the Marcella Street Home, an almshouse for children with 321 inmates, Parental School and School for Truants, with 149 inmates, a House of Reform with 144 inmates, and a large placing out department. At the time they took charge of these institutions they had no conception of the great opportunity of bettering them which was at once presented. Dr. Putnam described the conditions found in the institutions and what had been done to better them in the city of Boston. Further details would furnish more proof in favor of the argument that the work of this kind was in demand, and that it was incumbent upon the physician to share it.

The Position and Work of the American Pediatric Society in Regard to Public Questions.—Dr. THOMAS MORGAN ROTCH of Boston read this paper, which was an appeal to the Society to aid by its work and influence in safeguarding early life. He said that the chief point to be aimed at was to persuade investigators in connection with the different phases of early life that they did not know sufficiently all of the different sides of the various questions connected with children to allow them to control all of the work themselves. The workers who were endeavoring to reform the laws relative to child labor should understand that they had the appreciation of the medical profession. Dr. Rotch explained that when children had been rescued from the mills and workshops or sweatshops of various kinds of labor it was the province of the pediatrician what these children were able to do. After this had been decided the legal profession should inform legislators what laws should be made for the preservation of the child's health, in the sense of the child's life. The same reasoning applied to those who had charge of grading the schools, kindergartens, and physical sports of both girls and boys. The old method of determining the child's grade in school and the time when he should work was by chronological age, but children of the same age differed greatly in both physical and mental development. The judges and lawyers in criminal courts had told him that it was extremely difficult to find out how old children really were. A law might be made in regard to the age at which a child would be permitted to work in a mill, and yet in the mill would be found many children under the required age. The reason of this was because false returns were continually made, and frequently there was absolutely no record of when the child was born. Dr. Rotch said that for several years he had been endeavoring to find some more exact index, not a chronological one, but a developmental one. He thought they should be able to determine when a child should work in the mills by determining whether he had proper strength derived from adequate development for such work. The higher the development of the osseous system the greater the strength and resisting power of the child. He did not ignore muscles and the condition of various organs, and the physiological conditions of childhood, but they were accessories to the skeleton. The development of the epiphysis presented an important point so far as strength was concerned, and showed the stage of development of the child. These epiphyses could be studied in all joints, whether of the shoulder, elbow, knee, or ankle, but the joint that was easiest to reach and most practical for forming the anatomic index was the wrist. Out of some thousands of cases of children studied with the Roentgen ray it was shown that, in the vast majority of cases, the normally developed wrist so developed with the other joints. He therefore presented to the profession as an anatomic index the development of the wrist. This development could be carried on in successive grades from birth to fourteen years by making use of the osseous centers of the carpal bones and the epiphysis of the radius and ulna. For instance, having made a division alphabetically from "a" to "m," the Roentgen ray could be taken of the wrist of the child, and this picture would represent a certain stage of the child's development. In this way they could determine whether a child was ready to enter kindergarten, or a grade in school, and keep the place, what strain in athletics he should be allowed to undergo, and finally what form of work he was able to perform. An index of this kind would be entirely in the hands of the physician, and would not depend upon any statement of the parent. The results reached by Prof. Pryor of the State University of Kentucky tallied with his own. Prof. Pryor had pointed out, and his investigations had confirmed, that the development of the epiphysis, especially as seen in the osseous centers of the wrist, the degree of development varied in different races and in different families, but that members of the same family had very nearly the same development. The development of girls in the early stages of their existence surpassed that of boys in the same family. The osseous centers of the carpal bones and epiphysis of the radius and ulna appeared perhaps as much as one year earlier in girls than in boys. The precocious child with an undeveloped body should not be allowed to push up in the grades in school; such an individual should wait until his development equaled his mental condition. Dr. Rotch exhibited a series of pictures showing the development of the wrist at certain periods, corresponding to the kindergarten age, the school age, the athletic age, and partly how to decide upon different forms of labor. He showed how he investigated the findings in joints to determine whether there had been any inflammation in joints; such cases should be thrown out, even though the joint became normal again, because the congested condition of the joint caused the osseous centers to develop more rapidly in that joint than in the others. Dr. Rotch said that he wished to impress upon the Society that he in no way ignored other means of determining whether the child was ready to work or not. The development of the muscles and the functions of the organs should be taken into account.

The Need of and the Relation Between a Definite Anatomical Development and Child Labor.—Dr. LINNAEUS E. LAFÉTRA of New York said that he thought the American Pediatric Society should take the lead in devising a plan for safeguarding child life. The publication of the discussions of the Society in this matter would call the attention of editors and writers in the medical and lay press to the importance of the subject. The great difficulty in safeguarding the child lay in the non-enforce

ment of the laws in States where the laws were good. The physician should take part in the creation of public sentiment. A question which should be studied was, What was the minimum physical development for a child to have in order to undertake various kinds of work? The hours and conditions connected with different kinds of work should also be investigated. He was of the opinion that the keystone in this matter was the establishment of an age limit for compulsory attendance at schools, and the age of employment should be fourteen years. In New York state the law required documental evidence of age and a school course of not less than eight years. No child less than 60 inches in height, or weighing less than 80 pounds, should be employed; it would not be amiss to raise the weight to 90 pounds. A gynecologist had told him that he had found that shop girls were very apt to have an infantile type of cervix and an undeveloped uterus from standing too much during their early menstrual life Dr. LaFétra thought that size and weight were no indices of mental development.

The Need of and the Relation Between a Definite Anatomical Development and the Athletics of Early Life.—Dr. Samuel S. Adams of Washington presented this communication, and said that in his opinion the American Pediatric Society had never taken the stand that it should have taken in national affairs. He had been intimately connected with legislation, constructive as well as obstructive, for thirty years, and the result of his observation had been that the medical profession was more apt to be engaged in obstructing legislation than in constructing laws. If there was any body of men competent to speak upon questions relating to children, this body of individuals constituted an authority fitted to speak on national questions. After having existed for twenty-one years they had reached their majority, and should assume the position to which they were entitled. In speaking of the relation of a definite anatomical development to athletics, he said, that although a member of the medical faculty at Georgetown University and on the athletic committee, he was supposed to be simply the mouthpiece for the boys. Dr. Adams spoke of the effects of cigarettes upon boys during the developmental age, but it was very difficult to teach him the dangers so long as he found his father smoking when he went home. A genitourinary man had told him that almost invariably a young boy suffering from a venereal disease and under sixteen years of age was a cigarette smoker. As a rule, cigarette smokers drank beer. He thought the Society should take up this question at a future meeting and place their authoritative disapproval upon the use of cigarettes and beer during the developmental age. While connected with a boarding school in his neighborhood, he had never been consulted as to the development or fitness of those engaged in athletic work; that duty was assigned to an ignorant trainer. A decided stand should be taken as to the age at which a child should enter into athletics. The physician should have a general supervision over the children until they were sixteen or eighteen years of age. Questions concerning the child's health, whether local or national, should be left to the medical man, but he was the one to step forward. Every doctor should engage in the politics of his own town.

The Need of and the Relation Between a Definite Anatomical Development and the Grading of Kindergartens.—Dr. Isaac A. Abt of Chicago presented this paper. He believed that this anatomic index promised to be of great value in estimating the child's development. There was a great difference in kindergartens, and as much depended upon the teacher as upon the children. As yet they had no accurate method of calculating the physical status of the child in the kindergarten. He suggested that the anatomic index of the child should be controlled by a fatigue curve. More information than they had at present was needed before they rushed headlong into legislation. It was not the province of the Society to get tangled up in political affairs. They should first find out how they stood in regard to Dr. Rotch's work. The problems attached to the first period of life should be attacked before they took up the working age of children. He hoped Dr. Rotch's paper would stimulate some of them to attempt to place his results upon a firmer foundation.

The Need of and the Relation Between a Definite Anatomical Development and the Grading of Schools.—Dr. Charles Gilmore Kerley of New York said that the paper he had read at the last meeting of the Society had a bearing on this subject, and he read from a reprint what had special reference to the present subject. He thought that in a subject as broad as the one under discussion they should begin at the bottom of the matter and should see that instruction was given in the homes to parents as to how they should live and how they should bring up their children. The first five years of life were very important as related to the child's development; his nutrition, general care, etc., were most important as related to his career as a citizen. He referred to Dr. McDonald's statement that 35 per cent of the children in the public schools were defective and 15 per cent. non-educational—that was, that education was lost upon them. Dr. Kerley thought that statistics based on height and weight were unreliable, and should not be used as an index as to the child's capacity for work. In regard to whether the Society should consider the matter relating to child study in a general way, he was of the opinion that if they did not do it they would be compelled to sit by and see others do the work. The laws just passed in New Jersey on this subject were of value.

A Report of the Medical Work in the Juvenile Court of Chicago.—Dr. F. S. Churchill of Chicago presented this paper, which was based upon the examinations of 2758 children appearing before the Juvenile Court of Chicago during the past year. These children he divided into two groups, the dependent and the delinquent. A dependent child was one who had not efficient care. A delinquent child was one who had transgressed the law in some way or other. Seventy-seven per cent. of them were of foreign-born parentage. Among the dependents 90 per cent. were Americans, Germans, Polish, Italian, Bohemian, and Jewish, in the order named. Among the delinquents 95 per cent. were of the nationalities named plus Norwegians and French. The proportion to the total population showed that the Poles led. These children were examined as to abnormalities. Special attention was paid to height, weight, chest girth, condition of the tonsils, adenoids, conditions of the eyes, ears, teeth, heart, lungs, skin, and frequency of venereal disease. But little organic disease was found among them, but the percentage was high for carious teeth and enlarged tonsils, cervical glands, defective eyesight, ear affections, and gonorrheal diseases among the girls. As a probation officer was not allowed to bring a sick child to the court dispensary, there were practically no acute diseases. Both boys and girls of the dependent class during their earlier years ran close to the normal, although a little below. The older boys and girls among the delinquents were very much below the normal. This seemed to show that the strain and stress of life was beginning to tell about the age of puberty. The sixteen year-old girls averaged twenty pounds heavier than the normal girls. This was because all these girls were handsome, well-formed, and attractive to men who caused their downfall.

A Few of the Things Which the Pediatrist Should Teach.—Dr. P. J. Eaton of Pittsburg read this paper, in which he made a plea for common-sense teaching of pediatrics. He said that children were, as a rule, born

healthy, and yet many died before reaching the age of three years. The moral, mental and physical training of these children should begin at birth. Babies had a right to live, to be comfortable, and to grow, and all this depended upon enforcing certain rules from birth. The baby should have accurate and regular habits. Taking a bath, feeding, and then a nap was very simple, but it was worth while teaching. Children, too, should be taught to sleep. It was formerly said "the one who rocks the cradle rules the world;" now it was "the one who rocks the cradle spoils the world." The Lord knew best when He made breast milk for babies. Mothers and nurses should be taught what good milk was and how to obtain it. Mothers should be taught that the advice of a skilled medical man was far better than what was found in books. The less the baby was handled the better. More sensible clothing should be made for babies, and they should be given more fresh air in order that they might have plenty of oxygen for metabolism. After the first few days of life the baby should be in the open air and should sleep where there was a free flow of fresh air. In feeding the child a good rule to follow was that "things which needed chewing required teeth for grinding." Teething was a physiological process when it was normal, and if normal there should be no interference. If the gums were tough they should be lanced.

Dr. L. Emmett Holt of New York said that he felt sorry that so much time of the Society should be devoted to subjects of this nature, for he thought that the Society did its best work along research lines in matters relating to diseases of children. With regard to the anatomical index studies, he thought they should be controlled by observation of a number of people before this Society went on record as believing in them. The Society should not assume a positive stand before it had sufficient facts before it.

Dr. Rowland G. Freeman of New York said that he thought the work of Dr. Rotch was a very important one, and so far as it went should be accepted.

Dr. Charles Gilmore Kerley of New York expressed surprise at Dr. Churchill's figures. The number of children appearing before the Juvenile Court in Chicago was 2,758, while in New York in one year the number was over 11,000.

Dr. Churchill replied that this was the annual number that had appeared before the court since its establishment, and the number was decreasing rather than increasing. A number of protective leagues had been formed that went about the city uprooting dance halls, etc., and this did a very good work.

Dr. Walter Lester Carr of New York said that the Society had been organized to study children's diseases, and he was of the opinion that while as individuals they could do much good as members of committees, etc., the work of the Society should be carried on in a medical way.

Dr. John Lovett Morse of Boston said that he objected to the custom of making traction of the foreskin, and especially to circumcision. One should not mistake the normal for the pathological. If the prepuce was adherent, let it alone. Interference in most cases was unjustifiable.

Dr. Thomas Morgan Rotch of Boston said that the matter he had presented was only one factor of a problem which must be worked out. He said that in regard to devoting themselves entirely to medical subjects, it was recognized all over the world that prophylaxis in children was a great part of the work of the medical profession. He could not understand why what he had offered was called sociological; they were absolutely medical facts. In New York City there had been 10,000 children taken from the sweatshops and mills, and the good people who had done this should be told what to do with these children. How were judges and lawyers to decide what was best for these children unless the physician told them? He hoped to have what he had presented further investigated.

A Case of Cerebral Hemorrhage (Birth) with Operation.—Dr. Frank S. Meara of New York reported this case. A woman had passed through her first pregnancy in an uneventful manner, and as labor was slow it was decided to force matters. The cervix was dilated to about three fingers, bags were inserted, and chloroform administered. The forceps was not taken off, but was frequently unlocked to prevent undue pressure. The fetal heart was weak, and the child was with difficulty resuscitated, but with crying its color became good. In the evening of the same day it was found that there was facial palsy of the left side; the left arm was rigid and the hand flexed at the wrist. The left leg was also rigid, and there was exaggerated knee jerk. There were convulsive movements of the upper part of the body. The following morning the child was cyanotic and operation was undertaken. A clot was found and removed. No improvement followed, and the child died an hour later. The post mortem showed that in addition to the clot that was removed there was an extension of it along the fissure of Sylvius. This case emphasized the fact that if an operation was to be successful it must be performed at the earliest possible moment.

Dr. Alfred S. Taylor of New York presented the specimen, which showed the beginning of the hemorrhage around the outer edge of the Sylvian fissure, but there was an extension of the clot through the fissure of Sylvius towards the base of the brain, and an extension forward under the frontal and backward to the temporo-sphenoidal lobe, and a particularly marked extension downward to the front surface of the hind brain. Dr. Taylor showed some instruments that he had designed for this kind of work. The best cases for operative interference were those in which the clots were confined to the upper surface of the brain. The best evidence of the presence of clot in these cases would be the focal symptoms of the motor apparatus, pressure on the motor area. When the clot was situated at the base of the brain there would be pressure on the vital centers and respiration and circulation would be influenced. There was a question in these cases whether the child would be a useful member of society, even though he had good health. To obtain good results one should operate at the earliest possible moment.

Dr. L. E. La Fétra of New York said that one should look out for hemorrhage occurring shortly after birth where the cord had been wound around the neck. He had found in looking up the reports of the Sloane Maternity that a large proportion of the cases of cerebral hemorrhage had been those in which the cord was found encircling the neck.

Dr. Henry Koplik of New York said that the operation for cerebral hemorrhage in the newborn was one that required thought before undertaking it. It was often difficult to decide whether or not to operate.

Dr. John Lovett Morse of Boston said that he had observed the irregularity of symptoms in these cases, especially in the late development of symptoms. He had thought that they developed during the first ten or twelve hours, but there were reports of cases in which the first symptoms appeared on the third or fourth day. There were other conditions that gave the symptoms of cerebral pressure. In making a diagnosis of cerebral hemorrhage in the newborn one could not be too cautious. A bulging of the fontanelle indicated cerebral hemorrhage, and another symptom that had not been mentioned was the flowing of blood from the nose or the back of the throat, the

blood presumably coming from the cribriform plate of the ethmoid bone. Resort might be had to lumbar puncture in doubtful cases. Here there was a possible source of error in sticking the needle into a vein instead of the spinal. Even after deciding that a cerebral hemorrhage existed it was difficult to decide where it was located.

Dr. L. Emmett Holt of New York said that he had seen these children at the age of a year or fourteen months with the symptoms resulting from cerebral hemorrhage one felt justified in doing anything. He agreed with Dr. Morse, however, that the difficulties of diagnosis were very great. These hemorrhages were usually very profuse, and one could not be sure that all of the clot had been removed. The bulging of the fontanelle was the best single symptom in diagnosis. They should have localized symptoms; if there was general rigidity and convulsions they were very much in the dark. No importance should be attached to a bloody fluid in a lumbar puncture.

Dr. D. J. Milton Muller of Atlantic City reported the case of a child, seven months old, with every symptom of defective mental development. Six days after birth the child was seized with general convulsions and rigidity which lasted for five days. At various times he developed opisthotonos. Finally he got whooping cough and died. He thought there was some injury or hemorrhage of the brain. The post mortem showed the brain to be perfectly normal macroscopically, but microscopically there was a diffuse meningitis.

Dr. Charles P. Putnam asked the number of successful operations that had been recorded.

Dr. Taylor replied that Dr. Cushing of Baltimore had reported two successful cases out of four operated upon. The two cases in which he had been interested died shortly after operation. However, both were in bad condition before operation.

Dr. Roland G. Freeman of New York said that he had seen a case a short time ago in which the symptoms were very marked, but operation was refused. At the age of five months the child had improved and was still improving. There were no longer any convulsions and there was every indication that the child was getting well without operation.

Dr. F. S. Churchill of Chicago said that when one considered the results in these children one was justified in advising almost anything for their relief. Dr. Cushing had two cases which recovered after the operation; the two that died were not operated upon until some time after birth.

Dr. Samuel McC. Hamill of Philadelphia agreed with Dr. Holt in regard to the difficulty of diagnosis. He had seen a number of these cases. Many cases closely simulating cerebral hemorrhage showed nothing at autopsy. Where there were definite localized symptoms there had been no mistakes in diagnosis.

Dr. John Howland of New York said that even if a mistaken diagnosis had been made an operation was not necessarily fatal. He had seen one case in which nothing was found except an edematous brain. This child made a good recovery.

Dr. Alfred S. Taylor of New York said that he did not wish to be understood as saying that every child who developed cerebral symptoms should be operated upon. The subject of surgical interference should be studied from different standpoints. The dangers of the operation were apt to be magnified.

Dr. Meary of New York thought that fatal results in these cases might be attributed to delay in operating. Anatomical evidence showed that death might be the result of delay, the delay permitting further leakage and pressure upon the vital centers at the base of the brain.

Danger to the New Born from Gas Heaters.—Dr. F. W. Saunders of St. Louis said that in many houses no provision was made for the progress of the products of the progress of foul air, and it was to be hoped that builders might be influenced in this direction. Gas heaters were inimical to life in the new born. Many cases of cyanosis might be due to carbon monoxide poisoning. Dr. Saunders reported the case of a nurse and baby almost their death sleeping in a room from which a concealed gas heater burning low might.

Dr. Samuel S. Adams of Washington reported the case of a Government clerk who returned home to find his wife, mother, and baby dead from carbon monoxide poisoning from a coal stove. There had been several similar deaths in Washington since.

Spasmodic Stenosis of the Esophagus; a Case Demonstrated by the X-Ray. Dr. [illegible] of New York reported this case. He had seen this case, a child of sixteen months, last April because the child was suffering from attacks of vomiting. He was informed that on the third day after birth there was a discharge of dark blood from the mouth. Nursing was attempted for three weeks and then stopped. The vomiting or regurgitation occurred at or after every feeding. The child did well on artificial food for only a week and then regurgitated again. He learned that the vomiting occurred while taking food, seldom after. Two or three hours after feeding strings of mucus would be brought up. When the baby was one year old he weighed fifteen pounds. A tube was passed six and one-half inches when it met with obstruction. The baby vomited alongside the tube. He also vomited yellowish mucus along with fresh food after taking four spoonsful in the morning. This looked as though there was a pouch of some size along the esophagus. After feeding there was dullness on percussion to the right of the sternum. Radiograph pictures taken before and after eating were shown. The picture before eating showed nothing abnormal, but after feeding there was a shadow extending to the seventh dorsal vertebra. The stomach was apparently contracted with an hourglass contraction. This was a case of spasmodic stenosis of the esophagus and not of cardiospasm.

Dr. Thomas Morgan Rotch of Boston said this was a good instance of what the x-ray could do as an aid in diagnosis. He had seen one case of a pouch situated lower down in the esophagus. In this case the diagnosis was also made with the x-ray. His patient died of exhaustion.

Influenza: The Part It Plays in Hospital Infections; the Value of Cultures as a Means of Diagnosis; Influenza Carriers.—Dr. L. Emmett Holt of New York read this paper. He said that it was his opinion that the frequent infections that occurred in hospitals were due to influenza to a great extent. Experiments had been undertaken since January 1 to determine what value could be attached to throat cultures as a means of diagnosis. Cultures were taken from the throats of all the babies, nurses, and physicians in the Babies' Hospital. There were 312 cultures taken from 108 persons. Cultures were positive in 85, suspected in 42, not suspected in 43, and among these were 15 nurses. Cultures were negative in 112, suspected in 16, not suspected in 67, and among these were 28 nurses. Among the positive cultures the pneumococcus was positive in 53 and negative in 55. Among 202 negative it [illegible] the pneumococcus was positive in 30 and negative in 140. In 47 routine autopsies the following points were noted: Meningitis and lobular pneumonia, 8 cases, influenza bacilli positive in 2, negative in 6; the pneumococcus [illegible] negative in 7. Acute bronchitis, 2 cases, the influenza bacilli positive in 2, negative in 0; the pneumococcus positive in 1, negative in 1. In tuberculosis of the brain and lungs, 8 had meningitis. Pulmonary tuberculosis, 10 cases, influenza bacilli positive in 3, negative in 7; pneumococci positive in 2, negative in 8. Non-

tuberculous disease, 13 cases; influenza bacilli positive in 1, negative in 12; pneumococci positive in 4, negative in 9. Of 140 cases suspected, 43 gave positive and 97 negative results. Among the cases that were negative at the first culture 11 were afterward positive. The influenza bacillus was found in only 16 healthy individuals. The pneumococci were found in eight of these and were not found in the remaining eight. Klebs-Loeffler bacilli were found in four. Twenty-eight healthy persons showed neither the pneumococcus nor the influenza bacillus. When an otitis media was present there was great danger of looking at it as the principal disease. The organism was recovered from the heart's blood in no instance. Much depended upon the technique employed in taking the cultures. The influenza bacillus persisted in the bronchial secretions. Influenza was a large factor in house infections and was difficult to deal with.

Dr. Thomas Morgan Rotch of Boston said that one was apt to diagnose this disease before he should. It was a difficult disease to deal with. He referred to the work that was being done at the Massachusetts General Hospital in Boston. They there recognized that there was a clinical influenza, but their work seemed to show that the supposed organism was not the cause of the disease. It did not cause influenza any more than other organisms. They had found that 25 per cent. of the cases of common cold in the inter-epidemic periods, without the clinical symptoms of influenza, showed the influenza bacilli in large numbers. They concluded that the influenza bacillus must be excluded as a cause of clinical influenza. One had no more right to say that this organism caused influenza than that the staphylococcus, pneumococcus, or other pyogenic cocci caused the affection. Whether these results would be upheld later he did not know.

Dr. John Howland of New York said that in the recent epidemic of influenza it was very difficult to find the typical so-called Pfeiffer bacillus. There was, however, a large group of allied organisms.

Dr. Henry Koplik of New York spoke of the ambiguity of these organisms. A few years ago he took cultures of every child in his service, about 300, looking for the diphtheria bacillus. He found the diphtheria bacillus in the throats of 35, although they had no diphtheria. This had interested him in the ambiguity of the microorganisms.

Dr. Isaac A. Abt of Chicago said that in the hospital with which he was connected there would appear every now and then an epidemic of diphtheria. He had cultures taken of everybody's throat and found great numbers of the bacillus in the throat of one nurse; she had been responsible for the outbreaks of diphtheria. After being isolated for a while she was again permitted to return to the wards and another outbreak of diphtheria occurred; she was then sent away and the epidemics ceased.

Dr. Samuel McC. Hamill of Philadelphia said that in an institution in Philadelphia they had met with a number of infants who gave charts like those Dr. Holt had referred to and they had tried to determine the cause of the peculiar recurring temperatures. He had had cultures taken of the nasal secretions and had been trying to persuade himself that the temperature depended upon some infectious organism of a different type.

Dr. Thomas S. Southworth of New York said that there was a difference of opinion as to the exact organism responsible for this condition, but the fact remained that there was a clinical entity which by exclusion they were in the habit of calling influenza. During January, February, and March they had had a series of ward epidemics and the peculiar temperatures that were recorded during that time were apparently due to the ward epidemic going from child to child. In many instances these temperatures fell after paracentesis, and this led him to believe that some of these temperatures were due to otitic involvement. There was no question but that the disease was infectious. That this was the truth must be recognized in the future if they were to save these babies.

Dr. D. J. Milton Miller of Atlantic City said that he believed that the presence of the diphtheria bacilli in the throat was always a menace. One of the resident physicians of the hospital carried these bacilli in his throat for six or eight weeks when he got the clinical diphtheria.

Dr. L. E. La Fétra of New York said that he had stayed the hand of the aural surgeon from doing sinus and thrombosus operations as well as operations on the mastoid. They were too hasty in wanting to operate.

Dr. Henry L. K. Shaw of Albany told of an epidemic of influenza that occurred at St. Margaret's Home in Albany four years ago. The thought occurred to him to try to demonstrate the presence of the bacillus of influenza in the blood. The blood was obtained by pricking the temporal vein when the baby cried. They found that many of the cases called influenza were not influenza at all. Dr. Shaw reported a case of influenza meningitis.

Dr. F. S. Churchill of Chicago reported an instance of influenza meningitis occurring in twins four or five days old. At autopsy a very virulent meningitis was found and cultures showed a perfect growth of the influenza bacillus.

Pneumococcic Infection.—Dr. Walter Lester Carr of New York said that in croupous pneumonia and similar affections the pneumococcus might be recovered from the blood. He reported the case of a child, eighteen months of age, who had pneumonia followed by a marked invasion of the conjunctiva. There was a very marked pneumococcic infection, but recovery followed without any trouble. The child succumbed to an attack of meningitis six months after the attack of pneumonia. Many grippal affections were, in fact, due to the pneumococcus.

Report of a Case of Long-Standing Empyema, with a Note on Race as a Predisposing Factor in the Occurrence of Empyema.—Dr. Alfred Hand, Jr., of Philadelphia reported this case. This patient, a girl, three and one-half years old, weighing eight pounds and fourteen ounces, gave a history from which it seemed that the empyema had existed for about twenty months. The statistics of the Children's Hospital of Philadelphia for ten years showed that the number of cases of empyema among white children was about 10 per cent. of the pneumonias; among the colored children empyema occurred with less than 1 per cent. of the pneumonias. There were three cases of empyema among the colored race, but none of them showed the metapneumonic form. The case in question was a very uncanny sight. Resection of a rib was made under cocaine and pentrated one-quarter of an inch into thickened pleura. About one ounce of greenish pus was evacuated. About a month after, during the heated term, the child succumbed. In this institution there were 852 cases of pneumonias among white children and 99 of them had empyema, less than 11 per cent. Among 205 cases of pneumonia occurring in colored children only two had empyema or less than 1 per cent.

Dr. Roland G. Freeman of New York said that they had found at the Foundling Hospital that resection of a rib was entirely unnecessary in these cases.

Dr. Samuel S. Adams of Washington said that in the Children's Hospital in Washington from 40 to 50 per cent. of the cases were colored and among these he could not recall a single typical case of empyema.

Preliminary Report of Metabolism of Diphtheria.—Dr. John Howland of New York presented this paper, which was the result of his studies of the metabolism of diphtheria undertaken with the desire to investigate what metabolic disturbances might be produced during the course of diphtheria and throw some light on the obscure and fatal combination of symptoms usually ascribed to pneumogastric paralysis. There seemed reason to doubt that vom-

iting, abdominal pain, and slow pulse were due to degeneration of the vagus. If these symptoms were due to degeneration the nerve should be found normal when these symptoms were absent. Such was not the case. The pneumogastric nerve was found to be degenerated in practically every fatal case of diphtheria. These changes were found without regard to the associated symptoms. The nerve had been found degenerated in cases where there was no reason on clinical grounds to believe that it was affected. The vagus was found to be affected or degenerated at times when there were bacteriologically, no evidence of diphtheria and no clinical reason to suspect its involvement. The slowness of the pulse and the fact that atropine did not prevent bradycardia still further discredited pneumogastric degeneration as a causal factor. There was excessive excretion of urinary nitrogen in febrile affections. There were two factors concerned in this, the pyrexia and the infectious agent. It was difficult to find the one without the other. There was no strict parallelism between the height of the fever and the amount of protein destruction with its excessive nitrogen elimination. In general excessive nitrogen fell with the temperature, but it might continue for several days after the normal temperature had been reached. The study of several cases showed that during the course of diphtheria there might be a very great loss of nitrogen due to the effect of the toxemia alone, and this loss might continue far into convalescence. Coincident with the albuminuria there was a great loss of body protein which took place in the muscles and parenchymatous organs and probably in the kidney itself, and the albuminuria might be only an expression of the injury done to the kidney cells, rendering them less efficient for a time and permitting the serum albumin to pass through into the urine. In the destruction of muscles that took place in fever and cachectic processes creatin appeared in the urine. Very considerable quantities found in the cases reported indicated that the destruction of striped muscle was in progress. So far as the ammonia nitrogen was concerned there was nothing decidedly abnormal. There was nothing to make it appear that there was a marked and prolonged excretion of nitrogen evidently due to the toxemia that would have developed an albuminuria; there was evidence of great destruction of the body protein, and destruction of the striped muscle took place even when the temperature was normal as shown by the excessive creatin excretion.

A Case of Atresia of the Duodenum.—Dr. Roland G. Freeman of New York reported this case, which was the sixty-third of its kind reported. Although the cause of the condition was unknown, it had been attributed to syphilis and to pressure upon the head of the pancreas. This child was a male, born of a primipara, and was asphyxiated at birth. The child presented no untoward symptoms within twenty-four hours. On the second day it was noted that no urine was passed and dark green fluid was vomited. The child was jaundiced and mucus passed by the bowels. On the third day there was no vomiting, but the other conditions were unaltered. On the fifth day the vomiting continued and the jaundice was marked. Breast milk and a modification of cow's milk were tried. The stomach was washed out. On the sixth day the child did not seem fit for operation. The infant became decidedly worse on the ninth day and died on the tenth. The temperature had never been above 99°. The post mortem showed a small constriction above which the esophagus was dilated. The duodenum near the constriction was bound by adhesions. The walls of the stomach were thickened. The stenosis of the esophagus was complete; it was surrounded by connective tissue.

A Specimen of Formed Meconium Simulating Intestine.—Dr. Roland G. Freeman of New York reported this case, which he had seen in consultation for what was supposed to be a protrusion of the bowel from the anus. The protruded part had turned black. The child seemed to be in good condition. A cylindrical coil one-half an inch thick and eight inches long protruded from the anus. Its color was characteristic of meconium. He separated the coil by gentle manipulation and found it to be meconium.

Dr. Thomas Morgan Rotch of Boston said that congenital stricture of the duodenum was rather rare, but that cases having the symptoms of constriction of the duodenum were not so rare. It was important that a diagnosis should be made between pyloric obstruction, stenosis of the duodenum, and volvulus and twist of the intestine. If the diagnosis could be made many of these cases could be saved. Dr. Rotch had had a case of twisting of the omentum twice on its axis where operative procedure had relieved the condition. He believed in operative measures in children, but the great point was the making of a correct diagnosis.

A Case of So-Called Congenital Malaria.—Dr. Frank S. Meara of New York presented this paper. He said the question arose as to whether there really was such a thing as congenital malaria. Dr. Meara reported the case of a child, apparently healthy at birth, but who on the tenth day became sick and was brought to Bellevue Hospital with what was supposed to be a hernia. This supposed hernia proved to be the spleen, which filled one-half the abdominal cavity. The blood of both mother and child showed a tremendous number of malaria parasites. The child had either been infected in the ordinary way or else had been inoculated by the maternal blood in the act of parturition. The possibility of the separation of the placental membranes with inoculation following might be assumed. He believed that this was one more case of congenital malaria occurring during the act of parturition.

Some Considerations Concerning Scarlet Fever, Rubella, Scarlatinosa, and Duke's Disease.—Dr. D. J. Milton Miller of Atlantic City read this paper, which consisted largely of the histories of many cases.

The So-Called Thymus Death, with an Account of Seven Cases of Sudden Death in One Family.—Dr. J. P. Crozer Griffith of Philadelphia said that in April he had been called in consultation to see a child three months of age who had a bronchitis. The consultation was to discuss what might be done to prevent this child from meeting the fate that had befallen the preceding children. This was the seventh child in the family and was well nourished, having been breast-fed for three weeks and then gradually weaned. When three months of age the bronchitis increased and the diagnosis of mild bronchitis was made. The possibility of status lymphaticus was considered. Before long the lips and extremities became livid and harsh respirations appeared on both sides of the chest. The child soon died. The thymus gland was enlarged and the hyperplasia was marked. There was hypostatic congestion of both lungs, the heart was large, but without valvular lesions, and the bronchial and mesenteric glands and spleen were enlarged. In this family were eight children and all had died but one and practically with the same symptoms. Another was soon to be born and Dr. Griffith wished to know what could be done to save it. There was no evidence of tracheal compression in any of these children. The old theory regarding status lymphaticus was practically exploded. Among the theories advanced were the nonmechanical: (1) Defective secretion of the thymus with constitutional disturbances; (2) a neurosis of some sort; (3) a neurosis independent of status lymphaticus. The other theory advanced was the mechanical. This was due to (1) pressure upon the trachea; (2) pressure upon the cardiac nerve trunk; (3) direct compression of the trachea with strangulation. The views which seemed most plausible were that there was a neurosis of some sort which accounted for the cardiac death, and compression of the trachea due to strangulation. It was

wrong to attribute death to the thymus simply because it was found enlarged. There were evidently two classes of cases, viz., those due to mechanical obstruction to respiration and those due to nervous influences with cardiac failure and no evidence of stenosis. Dr. Griffith doubted whether an enlarged thymus had very great significance in cases of sudden death.

Dr. Thomas S. Southworth said that he believed that in time these sudden deaths would be ascribed to some disturbance of the internal secretions.

Dr. Henry Koplik of New York said that it was the tendency at present to group status lymphaticus and tetany in the same class. The clinical symptoms of the two conditions were very much alike.

Dr. John Howland of New York said that Warthin believed that as knowledge increased more and more cases of tracheal compression were being reported. Now the ordinary cases of sudden death with the pathological picture of enlarged thymus were so common that no one reported them any more. It seemed to him that they must consider enlarged thymus gland and enlarged lymphatic apparatus throughout the body as a common pathological finding. There were pathological, biological, and histological evidences to prove that the thymus gland was not a lymph organ.

The Stools of the New Born and Their Significance. Dr. Thomas S. Southworth of New York said, in summing up the present-day teaching on this subject, that after a period varying from three to at most five days the meconium gave way to yellow or orange-yellow stools, and these were of a uniform, homogeneous, semi-solid consistency; this was the normal stool, and any departure from this type indicated a disturbance of digestion or a deficient or unsuitable secretion of breast milk. Dr. Southworth said that his observations in the maternity wards of the Nursery and Child's Hospital were not in accord with this teaching. A table of statistics of 50 infants successfully breast-fed showed that the meconium lasted from 3 to 5 days on an average of 3½ days. In 14 cases the color was brown, appearing on the third to the fifth day, with an average of 4½ days; dark green in 31 cases, appearing on 4 to 7 days, with an average cessation on the fourth day; yellowish-green in 7 cases, appearing on 5 to 11 days, with an average cessation on the eighth day; greenish-yellow in 20 cases, appearing on 5 to 12 days, with an average cessation on the seventh day; greenish-yellow, soft residue in 28 cases, appearing on 5 to 18 days, with an average cessation on 8¾ days; yellow, soft residue, established 7 days in 18 cases, established 8 to 10 days, 15 cases; 11 to 14 days, 9 cases; over 14 days, 4 cases. Yellow and loose in 3 cases, continuing until 12, 19, and 34 days, respectively. The earliest stools of the infant consisted of meconium and were of a brownish-black color. They persisted for three or four days and were followed by bile-tinged mucoid intestinal secretion, which might be dark brown or brown-yellow, but was more commonly dark green, depending upon whether bile pigment was in the form of bilirubin or biliverin. A certain proportion might assume the classical color as the exception rather than the rule; the majority were greenish-yellow and more or less fluid, only becoming yellow later. Color consistency and fluidity followed no fixed rule. The importance of this variability lay in the prognostic and diagnostic significance which might be attached to them. Under the present teaching conclusions were most erroneous and led to steps that often were of serious consequence to the welfare of the infant. Personally he was of the opinion that the larger part of these variations were physiological, pending the establishment of complete harmony between the mother and the child in the extrauterine phase of nutrition. Dr. Southworth concluded that (1) the classical orange-yellow, semi-solid stools appeared in the majority of newly born infants at a later period than was usually stated; (2) considerable variations in color and consistency of the stools of newly born infants were compatible with regular gains in weight; (3) such variations in the stools for ten days or more even with slow or irregular gains in weight gave no certain indication that breast feeding could not be successfully carried on; (4) whatever the character of the stools, weaning was never indicated if the infant was gaining steadily in weight; nor even with delayed gains until intelligent efforts had been made to bring mother and child into physiological accord; (5) in the dark green stools of insufficient nutrition and not limited to the first few days of life there was a practical absence of all milk residue; (6) a yellow color of the masses of milk residue, when they were smoothed out precluded the assumption of indigestion, whatever the color of the exterior or of the surrounding media; (7) delayed gains in weight were often the result of factors which prevented the infant from securing a sufficient quantity of milk from perfectly competent breasts, and with patience and ingenuity these difficulties might be overcome.

The Urine in the Gastrointestinal Diseases of Infancy.—Dr. John Lovett Morse of Boston read this paper, in which were the results of the routine examination of the urine in 300 infants. All the examinations were made within forty-eight hours from the time of admission to the hospital; usually but one examination was made. It was thought that some findings of prognostic value might be found. He used the classification adopted by the pediatric department of the Harvard Medical School. Among 39 cases where the gastrointestinal disturbance was slight there was a slight trace of albuminuria in but 1 case. In 53 cases of chronic gastric indigestion, albuminuria was present in from 2 to 4 per cent. In 61 cases of chronic intestinal indigestion albuminuria was found in 11 per cent. In 17 babies with acute gastric indigestion albuminuria appeared in 3, or 17 per cent. In 70 babies with acute intestinal indigestion albuminuria occurred in from 4 to 6 per cent. Of 61 babies with infectious diarrheas albuminuria was found in 10 per cent. A review of his figures showed that albuminuria was present in about 8 per cent. of the babies suffering from chronic disturbances of digestion, never more than a trace of albumin was present, and almost never accompanied by casts. The presence of the albuminuria had no effect upon the prognosis. The presence of albuminuria had no effect on the prognosis in the acute gastric cases, but the mortality was higher in the intestinal cases having albuminuria than in those without it. Vomiting was more common in babies having albuminuria. Symptoms of disturbances of the nervous system were also more common in those having the albuminuria. However, there was nothing to show the connection between the disturbances of the nervous system and the albuminuria. Infection of the urinary tract in the symptom complex, as in pyelitis or pyelonephritis, was not common; in chronic disease there seemed to be no relation between the mortality and the albuminuria. Edema occurring in the course of gastrointestinal disease was not connected with the condition of the kidney.

The Irritating Effects of Cathartic Drugs on the Intestinal Mucosa.—Dr. Isaac A. Abt of Chicago said that the common practice of giving infants cathartic drugs for a more or less protracted period, whether their use was indicated or not, had suggested this inquiry. He hoped that he might be able to show that these drugs had a therapeutic limitation, and that the so-called cleaning-out process should not be continued after catharsis had been established. Cathartic drugs were administered about 125 times to 22 children to determine the irritating effects of the average dose of calomel, castor oil, and Epsom salts. The stools were examined before the administration of the drugs was begun. After the cathartic had been admin-

istered in varying doses for twenty-four hours, the stools were examined in the usual manner for color, odor, consistency, reactions, microscopic findings, the degree of oxidation, and bile pigment. Calomel was given to eight children and sixty stools were examined. The children who received one grain of calomel, either in single or divided doses, showed irritative effects on the following day, as was shown by the presence of mucus and occasionally of blood. Those who received from two to three grains of calomel at one dose showed both blood and mucus on the following day. This often persisted for two or three days. In those cases where calomel was given in divided doses (1/10 grain per dose) for a number of days the reaction for mucus and blood increased in intensity from day to day. Magnesium sulphate was given to five children and eighteen stools were examined. A small single does of one dram produced a slight irritation, *i.e.* a small quantity of mucus and blood. Large doses of magnesium sulphate showed at the conclusion of the third day a reaction for blood by the benzedine test, but not as much as was produced by the repeated doses of calomel. Castor oil was given to nine children, twenty-six stools being examined. Single doses of castor oil produced no irritation except a very slight one in one case. Two drams given to older children caused a reaction and irritation in but one case. Castor oil was given to two children in drachm doses for three successive nights; both of their stools showed reaction and irritation after the third day. Of the three drugs employed calomel seemed capable of producing the greatest irritation in the shortest time; castor oil seemed to produce the least reaction.

The More Frequent Use of Gavage in Pediatric Practice.—Dr. E. W. Saunders of St. Louis read a paper in which he argued that gavage should be used much oftener than it had been.

Soy Beans in Infant Feeding.—Dr. John Ruhräh of Baltimore described the soy bean (*Glycine hispida*) and said that a fuller account of the plant could be found in Farmer's Bulletin, No. 58, of the United States Department of Agriculture and the different varieties of Plant Industry, Bulletin No. 98. A gruel made from this bean, either alone or in combination with cow's milk, might be of value in certain classes of diseases, such as marasmus, and as a substitute for milk in diarrheas and in intestinal and stomach disorders and diabetes mellitus. He had not used it in a sufficient number of cases or long enough to justify further statement, but felt that in the soy bean we had a valuable addition to the dietary of the sick infant. The report was merely preliminary.

Congenital Cyst of the Liver, with Report of a Case.—Dr. Henry L. K. Shaw of Albany said that in an exhaustive review of the nonparasitic cysts of the liver by Moschcowitz in 1906 he was able to find only eighty-five cases; since that time three more had been reported. Two of these occurred in the fetus, seven in the new born, four in the first year, one eleven years old and the remainder in adult life. The largest number of cases were in persons over sixty years of age. Multiple cysts were found in all the cases occurring in infants, and in all cases there were abnormalities and malformations in other organs, most commonly degenerative changes in the kidneys. The case reported was that of a child, seventeen months old, who was well developed and weighed thirty one pounds. The mother had first noticed the "lump" last August, when it was about the size of an orange. Examination of the heart and lungs was negative and the lymph nodes were not enlarged. There was no jaundice. The abdomen was greatly distended, but not the abdominal veins. No positive diagnosis was made. An exploratory operation was believed to be both advisable and justifiable. Upon opening the abdomen part of the right lobe of the liver seemed occupied by a globular tumor which protruded downward to about the level of the navel. The tumor was punctured and about 900 c.c. of a clear yellow fluid withdrawn. The opening into the cyst cavity was enlarged and a rubber tube and drain introduced. There was practically no loss of blood and no evident shock. The fluid was found to contain a moderate amount of albumin and microscopically it showed only detritus, no cells or formed elements of any kind were found. Moschcowitz had concluded that these cysts were always associated with congenital anomalies of the liver consisting in aberrant bile ducts which might be extrahepatic or intrahepatic. The cysts had their origin in these aberrant ducts and might assume two forms, one arising from inflammatory hyperplasia of these ducts, the other by retention of fluid in these ducts, the result of congenital obstruction.

Abnormal Development of Bones.—Dr. Blackader of Montreal reported the case of a child of three years of age with a curious abnormal development of bones. The *x*-ray plate showed a peculiar arching of the bones. The circumference of each wrist at the joint was three and one-half inches, and of the foot five inches. The child weighed twenty-four pounds.

Election of Officers.—*President*, Dr. David C. Edsall, Philadelphia; *First Vice-President*, Dr. D. J. Milton Miller, Atlantic City; *Second Vice-President*, Dr. E. W. Saunders, St. Louis; *Secretary*, Dr. Samuel S. Adams, Washington; *Treasurer*, Dr. Charles Hunter Dunn, Boston; *Recorder*, Dr. L. E. La Fétra, New York. Next place of meeting, Washington, D. C., May 3, 4, and 5, 1910.

Puerperal Eclampsia and Leucocytosis of the Cerebrospinal Fluid.—Maurice Villaret and Leon Tixier describes a case of eclampsia occurring before, during, and after a six months' abortion, in which careful examination of the cerebrospinal fluid showed that there was present a leucocyte reaction in the fluid. There was no other toxic condition, and no nervous or infectious condition present. There was no nephritis. The arterial tension remained normal throughout, and the albumin disappeared rapidly after the cessation of the convulsions. Had there been uremia the tension would have been high and albuminuria maintained for some time. The author states that there are a certain number of cases of eclampsia in which hypertension of the blood-vessels cannot be considered a cause of the convulsions, and in these the presence of leucocytosis is in favor of a toxoinfective origin for the convulsions. *Gazette des Hôpitaux.*

Antibacterial Sera in the Treatment of Diphtheria.—Bandi says that therapeutic sera, in distinction from antitoxins, contain specific principles which opposes themselves to the vitality and reproduction of the bacteria. The author's serum is agglutinating and sensibilizing. Bacilli of diphtheria in contact with this serum when injected under the skin are rapidly destroyed by the phagocytes and undergo endocellular breaking down. It seems best to produce a polyvalent serum making use of different cultures of diphtheria bacilli, as is done with the streptococcus, so as to utilize differences of morphology and biology in these germs. The specific amboceptors obtained from the larger animal serum may be complemented by the use of alexic blood serum of man.—*La Riforma Medica*

The Rôle of Human Contagion in Infantile Tuberculosis.—J. Comby finds that tuberculosis is a disease that generally begins with aerial infection, from infected members of the infant's family. Prophylaxis should deal with removal of all tuberculous members of the family from the surroundings of infants, rather than with the sterilization of milk and the destruction of slightly infected cows. Milk, unless full of bacilli, will be digested and do no harm. But the grandparents who have chronic bronchitis and asthma, really tuberculous, will infect the child from their sputum. Children are born neither with tuberculosis nor with a predisposition to it. Remove the children of tuberculous parents at an early age from their home and bring them up in healthy surroundings and they will grow up healthy. Leave them with their parents and they will contract the disease. Pallor, emaciation, and narrow chest are symptoms of latent tuberculosis, not of predisposition to it. The measures taken against bovine tuberculosis, and to prevent the use of tuberculous milk, during the last twenty years have not diminished tuberculosis among infants.—*Archives de Médecine des Enfants.*

CRITICAL REMARKS ON EHRLICH'S SIDE-CHAIN THEORY OF IMMUNITY.*

By J. W. McLAUGHLIN, M.D.,

AUSTIN, TEXAS.

ACQUIRED immunity is a condition that gives protection to the organism from infection. The protection is specific in character, variable in degree and duration, may be developed by an attack of the disease immunized against, or by inoculations of the pathogenic agent, and is causatively associated with specific antibodies developed in the serum of the immunized animal, or with immunizing tissue changes wrought in the tissues of its body.

This criticism of the chemical or side-chain theory of acquired immunity is based upon evidence that the phenomena of immunity are not wholly results of chemical transformations of matter as claimed by the distinguished author of the theory, but are results of catalytic transformations; that the properties of a catalyst, including pathogens and toxins, are due to a physical or mass structure rather than chemical structure of the catalyst.

The evidence upon which these conclusions are founded will be discussed in this paper; an attempt will be made to show why and how a catalytic transformation differs from a chemical transformation, and why the phenomena of acquired immunity belong to the former and not the latter reaction. But to accomplish this it becomes necessary to describe an original theory of molecular energy, and its bearing on catalytic energy, which will be done; and finally to describe in outline an original theory of pathogenesis and immunization—a theory that is causatively based upon catalysis.

Forms of Energy.—It is recognized that all changes in matter which involve atomic and molecular arrangements belong to the domain of chemistry, but the forces which cause these changes to occur need not be chemical forces, they may be physical. Substances in stable equilibrium do not spontaneously undergo chemical changes; the conditions of equilibrium must be overcome before decomposition will occur. The forces which most commonly cause substances in stable equilibrium to be decomposed are the following: Mechanical energy, radiant energy (light and heat), electrical energy, chemical energy, and catalytic energy (ferment and pathogenic energy). While any one of these forms of energy may overcome an equilibrium of forces which bind together the separate parts of a stable substance into a whole, the manner in which it is done appears to be not the same in all instances. Mechanical energy—say the force developed by a concussion—may overcome a stable equilibrium by swinging the molecules of a substance beyond the limits of their attractions and decomposing them. Radiant energy may accomplish the same end by ether waves of light and heat. Electrical energy utilizes ionization to reach the same results. Chemical energy is the energy of atoms, and is the means by which chemical affinities react upon each other; an acid and a base are chemical affinities and their reactions afford an instance of the operation of chemical energy. Both the acid and the base are substances in stable equilibrium, but when they are brought in contact under favorable conditions they are decomposed. The energy of the atoms of the acid and base, in stable equilibrium in each substance and therefore latent, become active in atomic dissociation of acid and base, and cause the dissociated atoms to recombine into stable end-products.

The energy of a catalyzing agent is believed to differ from the energy of a chemical agent in origin and function: in origin, since it is apparently not derived from substances undergoing chemical changes, but from a catalyzer, whose "chemical make-up is the same after as before the reaction;"[1] and in function, since the catalyzer "directs the transformation along one path in preference to another,"[2] and determines the character of the end-products of the reaction.

The lines of chemical union pursued by nascent atoms in chemical reactions are those of least resistance. Atomic energy—set free as atomic force in the dissociation of matter—is the single influence which determines the line of least resistance in chemical reactions, but this is not the case in catalytic reactions, since, in addition to chemical forces, there is another force, that of the catalyzer, which takes part, and it may be the major part, in determining these lines.[2]

When chemical forces combine dissociated atoms of reaction along the line of least resistance it is plain that the presence of an outside force—the catalytic force—may change the resistance and direct the nascent atoms to pursue other lines of chemical union. As a matter of observation it is known that reactions produced in the animal body by enzymes (which are classified as catalyzing agents) cannot be produced by any chemical agent of known composition. For example, an enzyme inoculated into the tissues of a normal animal will cause an antibody—antienzyme—to appear in the animal's serum; furthermore, this antibdoy is specific since its energy will neutralize that of the enzyme inoculated, but none other. Likewise, inoculations of a species of bacteria, or a toxin into a normal animal will cause the appearance of specific antibodies to the bacteria or toxin in the serum of the animal treated; and it has recently been shown that specific antibodies will also appear in the serum of animals inoculated with an alien protein. Now, since neither ptomains, vegetable alkaloids, nor other substances whose chemical com-

*Presidential address, Texas Academy of Science, October, 1909.

position is known, are capable of causing the appearance of specific antibodies in the serum of animals inoculated with any of these substances,[3] the reactions produced by catalytic agents should not be classed as chemical reactions.

Specificity.—Reactions caused by ferments, pathogens, toxins and alien proteins are further differentiated from those caused by known chemical agents in "specificity." All reactions between chemical affinities are specific in a general way, but they lack the limitations in specific action which characterize the reactions of a ferment and its substrate, or the specific relations of a pathogen and its disease, or an alien protein and its antibody. A substrate may be vulnerable to but one species of ferment, an infectious disease may be caused by but one species of bacteria, an antibody to an alien protein is specific only to the exact kind and variety of protein inoculated. On the other side, an acid has an affinity for a base but this is not definitely specific as it has the same affinity for many other bases.* Of the many instances of definite specific affinity that ferments have for the substrate susceptible to its energy, that which maltase has for the α-glucoside will be cited. The α-methyl and β-methyl series of glucosides are chemical isomerides—the molecules of the two series of glucosides contain the same number and kind of atoms, but notwithstanding this maltase will readily ferment the α-group, but has no influence over the β-group of glucosides. Equally remarkable is the fact that emulsion will ferment the β-group but has no influence over the α-group.†

While the behavior of the ferment to the glucosides brings out the specific relations that exist between ferments and their substrates it does more, it indicates, although obscurely, the probable nature of the cause of this behavior. It has been conclusively demonstrated that the molecules of the two series of glucosides are identical in their chemical composition but are not identical in physical structure. Emil Fischer[5] says the atoms are differently arranged in space in the two series, "stereochemical configuration of molecules," and claims this is the sole cause of difference in behavior of the ferment, say maltase, toward the two groups of glucosides.

While this is doubtless true, the statement does not make clear why a feature of physical structure may determine the chemical affinities of a molecule; or, to be more exact, why the physical structure of a molecule may determine its form of energy, since chemical action is due to chemical force. But following the lead here given, I will try to show why a study of matter and energy, if logically followed up, will lead to the conclusion that the forms of energy which chemical substances manifest are derived from the chemical and physical structure of their molecules, and that an energy wave, here as it frequently is elsewhere, is an ether wave.

To make this conclusion good, it will be necessary to supplement the present knowledge of molecular structure and energy with the two original concepts, the sufficiency and pertinency of which will be clearly apparent. But not to anticipate, molecular structure and energy, as now understood, will be described and then the new features will be added. When this has been done it will become apparent that investigations into chemical phenomena need no longer be restricted, as they now are,[7] to describing "how" the elements combine; the outlook will be greatly broadened and chemical reactions made infinitely clearer by a comprehension of "why" the elements combine. Further than this, the terms "chemical affinity," "chemical forces," and the "internal forces of matter" will need no longer to be used vaguely to designate unknown but necessary forms of energy, as their origin and nature will be clearly revealed by the light of the new concept of molecular and atomic energy.

All substances are aggregations of molecules held together by attraction and yet in active motion, moving hither and thither, colliding, breaking into "ions" and atoms and recombining until the chemical forces, derived from the changing substances become equalized in molecules of the final products. "Theoretical chemistry," says Julius Thompson,[9] in the introduction to Thermo Chemical Investigations, "isbased upon the molecular theory according to which all substances are made up of molecules, and these molecules of atoms. The physical and chemical state of bodies depends upon the arrangement and motions of the molecules, and the other physical and chemical properties depend on the number and kind of atoms in the molecules, on their arrangement and relative motions."[7] A molecule is the smallest part of a substance which retains its properties. It is made up of atoms, which vary in number and kind according to the physical and chemical properties of the substance they compose, and these are spatially arranged within the molecule in characteristic groups, and vibrate in periods that distinguish one kind of atom from another kind of atom. This molecule we must take as the representative of matter, for all masses of it, whether gaseous, liquid or solid, are but aggregations of similar bodies.

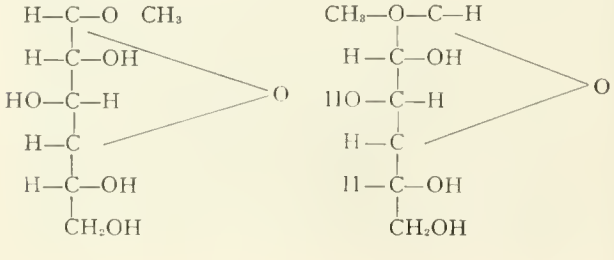
Atoms are chemical units. Modern chemistry

*"One of the most popular arguments against the view that fermentation is nothing more than a simple process of hydrolysis is that while starch, albuminoids, glucosides and sugars can be hydrolyzed by dilute acids, under approximately the same conditions, each ferment exerts its own specific action. The diastase which hydrolizes starch will not 'touch' albuminoids, maltase, nor cane sugar; and the ferment which breaks up albuminoids does not affect the carbohydrates or fats. In 1860 Pasteur proved that while mould fungus readily induces the fermentation of dextro-rotatory tartaric acid, it has no action on the lævo acid. And Emil Fischer has given us many examples of sugars, one isomer of which is susceptible to attack of an enzyme while the opical isomer is immune."[4]

†In 1894 Emil Fischer,[5] by his classical researches upon artificial and natural glucosides and their related enzymes, largely extended our knowledge in this field. D-glucose (dextrose) is known to exist in two stereo-isomeric forms, and Fischer found that when it is dissolved in methyl alcohol containing hydrochloric acid two stereo-isomeric methyl glucosides are formed, according to the following equation:

$$C_6H_{12}O_6 + CH_3OH = C_6H_{11}O_6CH_3 + H_2O$$

According to Fischer these glucosides have the following formulæ, which are identical except as regards the spatial position of the — O CH_3 and the — H radicals attached to the carbon atom. This difference of configuration is quite sufficient to determine their reaction with enzymes, for Fischer found that one of them, which he called the α-methyl glucoside, was readily split up by yeast maltase into glucose and methyl alcohol, whilst the stereo-isomeric β-methyl glucoside was not attacked at all. Emulsin, on the other hand, splits up the β-glucoside, but not the α-glucoside."



teaches that atoms are not single but composite bodies, made up of a great number of infinitely smaller bodies—corpuscles—whose dimensions do not exceed the ten-thousandth part of a hydrogen molecule. That these infinitely small bodies carry energy with themselves in the make-up of atoms is an evident conclusion and a necessary one to explain atomic energy, since atoms are actively moving bodies, whose vibrations occur in periods that characterize each particular kind of atom. Spectroscopy would not be intelligible but for this fact.

Professor J. Clerk Maxwell[8] suggests that "Atoms exist of various kinds, having their various periods of vibrations, either identical or so nearly identical, that our spectroscopes cannot distinguish them." "The same kind of atom, say of hydrogen, has the same set of periods of vibration, whether we procure the hydrogen from water, from coal, or from meteoric iron." Lord Kelvin, in his vortex hypothesis, not only attributes to each kind of atom distinctive motion, but holds that the motion of the atom may be the sole character which distinguishes it from other atoms.

When to molecular structure, as here described, is added the knowledge that heat is developed by molecules in their translations and collidings, and that heat may be transformed into other forms of energy, we have before us the teachings of our textbooks of molecular structure and energy. And in view of the meagerness of this knowledge and its insufficiency to furnish a working hypothesis of the cause of chemical action, no other course is left to chemistry than that of describing "how" chemical changes occur, and to describing transformations of matter as they are seen from the viewpoint of changing matter, but not as they appear from the viewpoint of energy.

Taking up the study of molecular structure and energy where it has apparently been abandoned, I will supplement our knowledge of the subject by adding to it two new features. The first of these is the presence of the universal ether, surrounding the atoms in the molecules and accurately reproducing as ether waves the vibrations which distinguish them. The second is an adjustment of conflicting ether waves, produced by the vibrating atoms in the molecules, and their transformation, by the "principle of interference" into waves whose periods coincide in crest and trough; that is, into waves of energy.

The mutual neutralization of the waves of light as seen in Newton's rings when the crest of one wave falls upon the trough of another, or the neutralization of two sound waves, one by the other, affords an example of the "principle of interference," which occupies an important place in the new concept of molecular energy. "For beauty, simplicity and wide application, this principle," says Sir John Herschell, "has hardly its equal in the whole circle of science."

The set of adjusted intramolecular waves accurately represents the following factors of their synthesis—the kind and number of atoms in the molecule, their arrangement in space, the character of ether waves produced by their vibrations, and the results of their adjustment. They also possess energy, since the wave impacts, recurring in coincident periods millions of times per second, are capable of doing work.

Catalytic Energy.—Since the properties of a substance are due to the chemical and physical structure of its molecules, and the energy of molecules is derived from ether waves which represent their chemical and physical structure, we may safely assume that a molecule cannot influence other molecules through its waves of energy (potential energy) until the waves come in contact with waves of other molecules they can either exaggerate or neutralize, when potential wave energy is converted into an active force—dynamic energy. But it is evident that the molecules of the interior of a mass are conditioned differently from those occupying the surface; the waves of the former are mutually equalized, while the waves of the surface molecules are not equalized, since there are no opposing molcules to supply opposing waves. It follows, therefore, that (1) a perfect equilibrium of molecular waves of a mass is not possible, as it would require mass without surface; (2) molecular energy not equalized is available as potential energy; (3) the quantity of potential energy of a mass that may become available without decomposition of the substance is directly proportional to the extent of its surface and inversely to its mass; (4) available molecular energy should be capable of decomposing substances weaker in chemical bonds and of coincident periods (*a*) in practically unlimited amount, and (*b*) the dissociating force should be a factor in determining the line of union along which dissociated atoms combine; (*c*) work done by molecular surface energy need cause no chemical change in the substance whose molecules supply the energy.

It has been shown by Bredig and von Berneck[10] that ultramicroscopic particles of platinum are torn loose from platinum terminals immersed in distilled water, by the electric current, and that these infinitely small pieces of platinum suspended in distilled water, a colloid solution, possess in a marked degree the properties of ferments. Now, since the only difference between the minute and larger pieces of metal is in an immensely increased surface given to the mass by dividing it into infinitely small pieces, it must be the enormously increased molecular surface, with a corresponding increase of potential energy, that give the ultramicroscopic particles the property of ferments.

It is not necessary for me to say that the properties or functions described are identical, as far as they go, with those of a catalyst, and if the argument and premises submitted are logical and sound, a catalytic agent is a substance whose extent of molecular surface is greatly exaggerated and largely out of proportion to the mass. This seems to be a characteristic of colloids to which enzymes and toxins belong.

The following summary of accepted catalytic properties comprising Mellor's "Articles of Faith," show how close together are the properties of a catalyzer logically deduced from our concept, and those recognized by science. Mellor says:[9] "What part the catalyst plays in the reaction is shrouded in mystery." The following, however, are generally recognized as "articles of faith": (1) The catalyst has the same chemical composition at the beginning as at the end of the reaction. (2) A small quantity of the catalytic agent is sufficient to effect the transformation of an indefinitely large quantity of the reacting substance. (3) The phenomenon of catalysis is universal. "There is no kind of chemical reaction," says Ostwald, "which cannot be influenced catalytically, and there is no substance, element, or compound which cannot act as a catalyzer." (4) The activity of a catalytic agent depends on its physical condition. As a rule the finer its state of division the greater its activity. (5) The function of a cata-

lyzer is to direct the transformation along one path in preference to another.

The new theory of atomic and molecular energy may at first sight appear to violate the principle of conservation of energy, for the reason that persistent motion, involving a constant expenditure of energy, is ascribed to atoms with apparently no evidence that energy is received. But since it has been shown that atoms are complex bodies, and are made up of a great number of infinitely smaller energetic bodies which bring energy with them in the make-up of atoms, atomic motions are not in violation of the principle of conservation of energy. Besides, if atoms do not vibrate, and in characteristic periods, what about spectroscopy and the undulating theory of light, and how can the action of radium be explained? The quantity of energy given off by radium is enormously out of proportion to the chemical change that takes place in the substance; and it may, therefore, be asked, where does radium get its energy?

Specific Antibodies.—While it is recognized that "the function of a catalyzer is to direct the transformation along one path in preference to another," it has not yet been made clear by what means the catalyst does this; nor is it explained why the end-products of the transformation are antibodies to the catalyzer. But when catalysis is examined in the light thrown upon it by the new theory, it is believed that a reasonable explanation of these problems will appear. A mental picture of a catalyzer in action will show that its waves of potential energy (its molecular waves), the intensity of which is proportional to the largeness of molecular surface and the smallness of the mass, falling millions of times, crest and trough, on molecular waves of the substrate, will swing the molecules of the substrate beyond their attractions and disrupt them. And since nascent atoms combine into stable end products, the influence of wave energy of the catalyzer in the recombination of the atoms must be considered, as it seems evident when this energy dominates the reactions no end-products can form whose molecular waves coincide with those of the catalyzer, since coincidence will cause dissociation. The less the waves of the two sets, catalyst and end-product, coincide in crest and trough, the easier can the atoms combine, and when the trough of the waves of the end-product falls upon the crest of the waves of the catalyzer, the line of least resistance will have been found; but *the end-product will be a specific antibody to the catalyst.*

To be in harmony with this scheme each molecule of the final product of a catalytic reaction should be a specific antibody to a molecule of the catalyst; but since the available energy of a substance as a mass is a matter of surface action, the neutralizing energy of an antibody should be directly proportional to a maximum of molecular surface with a minimum of mass: as an extent of molecular surface may be large or small, end-products of catalytic reactions which have exaggerated surfaces in proportion to mass are active antibodies, while end-products which do not possess these features are less active.

It was stated in the beginning of this paper that specific antibodies are recognized by common agreement as a cause of acquired immunity; and since reactions in which antibodies appear as end-products are shown to be catalytic, the appearance of specific antibodies in the serum of a normal animal recently inoculated with bacteria, toxins, enzymes, or alien proteids, affords strong evidence that these bodies are catalytic agents, and that immunizing reactions produced by inoculating a normal animal with one of these bodies are catalytic reactions. This inference, if a stronger term is not justified, is much strengthened by failure of chemical agents to produce antibodies in the serum of animals inoculated with such agents, and by failure to show that the peculiar forms of energy of enzymes and toxins are causatively connected with chemical composition of the substances. Analyses of enzymes and toxins have found nothing but protein; no ferment or toxin has been separated in a pure state.

Oppenheimer[12] says, "We must be content to assume that they (toxins) are large molecular complexes, probably related to the proteins, corresponding to them in certain properties, but standing nearer to the equally mysterious enzymes, with whose properties they show the most extended analogies, both in reactions and in activities." And he further says,[13] "Of the ways and means by which the peculiar forms of energy of ferments develop their activity we have not the slightest trustworthy idea." But when toxins are classified as catalytic agents, and pathogenesis is classified as a catalytic reaction, in which a pathogen or toxin plays the rôle of catalyst, it is but necessary to find in the sera of normal animals vulnerable substrates, to explain rationally how bacteria and toxins cause infection.

Recalling to mind that stereochemical configuration of molecules of the α-glucoside made it vulnerable to the ferment (maltase), while a chemical isomeride—the β-glucoside—is not vulnerable to this ferment because the atoms of its molecules are differently arranged, we should seek in blood serum for a substance whose molecules are arranged in homologous groups, which retain the chemical features of the substance but differ among themselves in stereochemical configuration. When a substance of this nature is found, we will have a substance whose molecules will be susceptible to many species of bacteria and many toxins: each group of homologous molecules, while retaining the chemical character of the whole will differ in physical structure, and because of this the groups will differ in specific vulnerability; one group will be vulnerable to one species of pathogen, another group to another species, and so on down the list.

Now the albumins of the tissue juices apparently possess the characters we are seeking. The albumins compose the larger part of the tissues of the body and the various cells obtain from the albumin molecules of the serum nourishment they require for the repair of waste and for functional action. It seems impossible to understand how cells of various kinds can obtain from a homogeneous substance materials so heterogeneous, but when we conceive the molecules to be arranged in many groups of albumin isomerides, the process of assimilation becomes catalytic and falls within the scope of mental action. Likewise, the problem of infection becomes a matter of easy solution, since each group of homologous molecules may be a specific substrate to a single species of bacteria, and, therefore, susceptible to disruption and conversion into specific toxalbumins by the molecular energy of this species. Pathogenesis is, then, a catalytic reaction in which a pathogen plays the rôle of catayst, a group of proteid molecules of the serum the part of substrate, and the end-product that of antibody. In this process the albumin molecules of the substrate are converted into toxalbumins (the poison of infection) by the pathogen or toxin.

The Side-Chain Theory.—Following the classification of Ehrlich, acquired immunity will be discussed under two headings—toxic immunity and bacteriolytic immunity. The term "toxic immunity" designates immunity against a bacterial toxin, or the disease it may cause. It gives no protection against diseases other than those caused by toxins, and is, therefore specific, as the neutralizing energy of the antitoxin is limited in its action to the toxin of the disease. The term "bacteriolytic immunity" designates immunity of the organism against a species of pathogenic bacteria. Bacteria which invade the immune organism may be killed by bacteriolysins which appear in the serum of the animal during its immunization; this action is specific, as the *lytic* energy is effective only against the one species of bacteria. Since antitoxins, which appear in the serum of animals during immunization, are recognized as the cause of antitoxin immunity, and their origin and synthesis are not known, it is the province of theory to explain these problems. It is likewise, and for the same reason, the province of theory to explain the synthesis of bacteriolysins, and how they kill bacteria, since these matters are not known to science. In discussing the features which differentiate catalytic from chemical reactions I submitted some speculations on antibodies which include antitoxins and bacteriolysins, and will have more to say later when on the subject of immunity. In the meantime the following brief outlines of Ehrlich's theory will be submitted:

Toxic Immunity.—It is taught in the side-chain theory that antitoxins are chemical agents which specifically neutralize poisonous toxins; that a toxin molecule has two groups of chemical affinities—a haptophore group and a toxophore group; that the toxin molecule must be bound to the side chain by the haptophore group before the poison side or group can reach and destroy it. And, since the affinities of toxins are specific, it is taught that the affinities of the binding or haptophore groups are both numerous and varied in order that they may be chemically attracted by the corresponding affinities of the side chains. This feature is illustrated diagrammatically by representing the affinities of the side chains as objects of many shapes, and the affinities of the haptophore groups as receptors shaped to fit in the side chains, as a key fits its lock.

The tissue cells of the body are described as having a central fixed substance of organic life, with surrounding molecular groups, which constitute its side chains. It is assumed that the side chains are clothed with chemical affinities of many kinds to enable them to select nourishment suited to each kind of cell; and that the specific affinities which enable the cells to select food molecules for cell nourishment also enable the affinities of the side chains to fix toxin molecules which infect the organism. The theory further teaches that tissue cells which have been poisoned but not destroyed by toxin molecules throw off the injured side chains and reproduce others identical with those lost. And it is furthermore assumed that side chains destroyed are reproduced in larger number than the cells can place; and that the excess passes into the blood, where they maintain an independent existence. The outcome of this is that the side chains floating in the blood stream are described as specific antibodies to the toxins (antitoxins), since they can fix and neutralize these bodies (toxins) in the blood stream, and so protect the cells of the body from becoming poisoned by the toxins.

If the merits of this beautiful theory are alone determined by its ability to explain the phenomena of toxic immunity the verdict should be highly satisfactory. But since there is no proof that toxins are definite chemical agents; that separated portions of cell structures (antitoxins) are capable of maintaining an independent existence in the blood; and that Nature departs in this instance from her simple uniform methods to adopt others that are bewilderingly complex and without parallel; and since the phenomena of immunity may be rationally explained without accepting these hypotheses, the verdict should be—"not proven."

I have read that in the commercial production of diphtheria antitoxin (from the horse), a unit of toxin will produce ten thousand units of antitoxin, and the quantity of antitoxin may be further increased, and very largely, by frequently bleeding the animal. While I cannot vouch for the accuracy of these proportions, it is evident that the large number of units of antitoxin which may be produced from a single unit of toxin takes the process out of the realm of chemical action and places it in the domain of catalysis, or ferment reaction. Besides, the fact that inoculation of a known chemical agent does not produce an antibody in the serum of the animal treated should be conclusive that the production of antitoxin by toxins is not, strictly speaking, a chemical process.

The catalytic theory of toxic immunity stands out in favorable contrast to the chemical or side-chain theory in simplicity, uniformity, extent of application in physiological processes of the organism, and in experimental proof furnished by development of specific antibodies in the serum of normal animals inoculated with the toxin. The production of antitoxins in the blood serum, as seen from this point of view, is as follows: The toxin, being a catalytic agent, will cause a catalytic reaction when inoculated into a normal animal—a reaction in which the toxin is the catalyzer, a group of vulnerable proteid molecules is the substrate, and the antitoxin is an end-product.

Bacteriolytic Immunity.—It is claimed by the side-chain theorists that the animal organism owes its protection from invasion by pathogenic bacteria to two soluble substances contained in immune serum—alexin and immune body. The name "alexin" was given by Buchner and the school of humoralists, who taught that alexin is the principle that gives blood bactericidal properties. It is a normal constituent of serum; is destroyed by heating to 55° C.; enters into chemical combination and may be substituted by chemical agents; is nonspecific in action, and is regarded as a mild ferment, but this has not been definitely established and is of questionable accuracy. "Immune body" is a term long used to designate a substance, contained in immune serum, that is an important factor in acquired immunity. Unlike alexin, immune body is not a component of normal serum; is not destroyed by heating to 55° C.; and is definitely specific in its action. Immune serum then contains two substances—alexin or complement, and immune body or amboceptor, which acting together supply its bactericidal power, according to the side-chain theory. Neither one of the above is bactericidal alone, but they become so when they act together.

This was determined in the following manner: It was first shown by experiment that immune serum is specifically bactericidal; the serum was then heated to 55° C. when it was found to have

lost its bactericidal power; but this was fully restored by adding to the inactivated (heated) serum fresh (unheated) serum. It is claimed, therefore, that heating immune serum to 55° C. destroys the complement it contains, and that this is restored and the serum made active by the addition of complement contained in the fresh serum. But since activation of immune serum may be accomplished by adding fresh normal serum of animals of different species, it is evident that the required substance contained in the added serum is not specific.

Now the problem to be solved is—how immune serum destroys bacteria, why the action is specific, and why coaction of fresh serum and immune body is necessary to secure this result. The answer to these questions by the side-chain theory is as follows: The two soluble substances of immune serum to which it owes bacteriolytic efficiency are complement and amboceptor. Complement is the name given alexin on the hypothesis that it is complemental to amboceptor in destroying bacteria; it has all the characteristics of alexin and is alexin. It is assumed to have two groups of affinities—a haptophore group—which unites it to the amboceptor, and a zymophore group, which supplies the "lytic" ferment that destroys the bacteria. Amboceptors are hypothetical bodies of immune serum, whose function is to unite complement and bacteria in the serum. The name amboceptors was given to these bodies on the supposition that they have two receptors, one for complement and the other for bacteria. The complement receptor has no specific affinities, but the bacteria receptor has a multiplicity of affinities in order that it may fix bacteria of many species. It is quite evident, when the existence of complement and amboceptor is agreed to, why neither complement nor amboceptor alone is effective in destroying bacteria, but become so when they act together, since complement must be anchored to the bacteria by amboceptor, an intermediary, before complement can reach and poison the bacteria.

It is, of course, understood that this explanation is a theoretical conception, beautiful, consistent, and sufficient, but only a theory, and as such is open to fair criticism, without reflecting upon its distinguished author. Do amboceptors, so vital to the side-chain theory, exist, or are they objects conceived in fancy to explain conditions? If they have an existence the fact has not been proven; they have never been isolated, and nothing is known of their composition, place of origin, or synthesis. It is true that immune body is a constituent of immune serum and its identity with amboceptor has been claimed; but to allow this claim would, it seems to me, destroy the chemical theory, since it has been shown that immune body has never been produced by known chemical agents. Besides, when we consider the functions ascribed to amboceptors, it is hardly possible to believe they are chemical agents, since we have no evidence that such agents possess the power of reproducing themselves, as amboceptors must do in order to repair losses sustained by combinations with bacteria; or of remaining long in the system, since these foreign chemical agents would quickly be eliminated or destroyed, as other foreign substances are.

It seems but fair that a theory should not only be capable of giving a rational explanation of phenomena, but its premises should have a basis of truth in fact or analogy; and since the side-chain theory does not fully comply with these requirements it seems unwise that it should be accepted.

There is still another defect in the side-chain theory that exposes it to fatal criticism as a theory of acquired immunity, it is this: it offers no explanation of *lasting immunity*. The term of acquired immunity is not the same for all infectious diseases; some never recur, others may recur after the lapse of years, and others may recur every time the person is exposed to the infection. The two types (toxic and bacteriolytic) made to cover the field of acquired immunity described in the side-chain theory are both short lived forms and necessarily so since the causes of these types (toxins and bacteriolysins) do not remain in the body, but like other foreign substances are soon removed or encapsulated.

Since immunity does not outlive the causes of its origin, the bacteriolytic and toxic forms, which are caused by specific antibodies in the serum, are of short duration and disappear with the disappearance of the causal antibodies. But there is a large number of infectious diseases which are thought not to be toxic in origin, since no soluble toxins have been found in the serum or other tissues of the infected body; and in which immunity is not due to bacteriolysins. A feature of this class of infectious diseases, and one which distinguishes them from toxic and bacteriolytic diseases, is the lasting character of their immunity. Immunity against yellow fever, for example, is lasting and may continue a great number of years, or for life, while immunity acquired against a toxic disease, say diphtheria, is of short duration. The nature and cause of lasting immunity are apparently not embraced within the scheme of the side-chain theory, and I venture, therefore, to submit in brief outline an explanation of acquired immunity which will cover all its types, and is predicated on the concept of atomic, molecular, and catalytic energy, already described.

Pathogenesis, or the process whereby an organism becomes specifically infected, is, according to the new theory, a catalytic reaction occurring within a living nonimmune organism. In this reaction a species of pathogenic microorganism, its toxin or endotoxin, is the organic catalyst, and a group of homologous molecules of the serum (stereoisomer of protein) is the substrate. The molecules of the substrate are dissociated by the wave energy of the organic catalyst, and the nascent atoms, under the dominating influence of this energy, combine to form specific antibody—a toxalbumin—which is the specific cause of the resulting infectious disease.

The type of an infectious disease produced by a reaction of the character described will depend, first, on the specific cause, and second, on the stereochemical configuration of the molecules of the substrate. Specificity characterizes the reaction throughout, as every type of infectious disease has a specific cause; every organic catalyst requires a specific substrate, and every antibody is a product of a specific reaction and possesses specific energy. The duration of immunity obtained in this process will be permanent if the reaction is complete—that is, continued until all substrate (molecules susceptible to dissociation by the catalyst) is transformed. But this seldom happens, as a concentration of antibody (end-product whose energy waves antagonize those of the catalyst) brings about an equilibrium of forces that stops the reaction before the substrate has all been transformed. It would appear, therefore, that the end accomplished by antibody is to afford temporary immunity; and we must seek

further to find the tissue changes of lasting immunity.

The dependence of coaction between an enzyme and the substrate vulnerable to its energy upon definite relations in the structure of the molecules, has been determined by many observations, and is a *sine qua non* of catalysis according to the new theory. Therefore, when it is shown that the portion of substrate left untouched by the catalyst in a toxic reaction becomes changed in the structure of its molecules—is transformed into a stereoisomer of its substrate—it becomes plain that the transformed substrate is immune to the pathogenic agent to which it had previously been susceptible; and, further, that immunity thus acquired will be lasting, since the transformation has merely changed protein into an isomer and not into a foreign body.

Now, evidence in the case of enzyme reactions proves that these reactions are reversible and that the reverse product is an isomer of the substance transformed. If, therefore, the analogies in structure and in reactions between enzymes and toxins, justify the belief that pathogenic reactions are also reversible, a rational explanation of acquired immunity will be found in the transformation of a pathogenic substrate into an isomer of the same substance; since the isomer will be immune from dissociation by the pathogenic agent. The principle on which this fact is based is illustrated in the immunity of the β-glucosides to maltase notwithstanding the susceptibility of its stereoisomer—the α-glucosides to this enzyme.

According to the hypothesis of Van't Hoff[14] an enzyme will synthesize only the bodies which under other conditions it can hydrolyze. If this is correct the scheme of lasting immunity just described must fall to the ground since it is evident that a substrate which may dissociate (hydrolyze) the toxin is not immune to this agent; in fact a substrate of this structure may be hydrolyzed by the enzyme in a direct reaction as often as it is synthesized by it in a reverse reaction. But as a matter of fact this does not occur, and when Croft Hill,[15] the first to bring forward definite proof of a synthetic process taking place under the influence of an enzyme, discovered that revertose, afterward shown to be isomaltose (which is not vulnerable to hydrolysis by maltase) is the product of the reverse reaction of maltase on máltose, he was greatly surprised, since the result seems to be in violation of the Van't Hoff[14] hypothesis. This and other results of the same character led Franklin Armstrong[17] to conclude that an enzyme as a general rule synthesizes exactly those bodies which it cannot hydrolyze. This conclusion is in perfect harmony in its results with the scheme of immunity we are describing, but there seems to be a difference of opinion between us as to the nature of a reversible reaction—the exact process by means of which these results are obtained.

The generally accepted opinion, as I read it, is that a reversible enzyme reaction is one in which the same enzyme acts reversely to its direct action, while the process, as I reason it out from an energy point of view, is one in which the antibody, when added in excess of the quantity produced in the reaction, is the enzyme which transforms the substrate into an isomer of the same substance of which the substrate is composed.

Taking for illustration the process in which maltase transforms maltose into glucose, I would explain the reaction as follows: Relations in molecular structure held in common by maltase and maltose create ether waves of energy (molecular waves) in each substance which coincide, crest and trough, in periods; and as a result of this coincidence the waves of maltase fall in concident time millions of times a second on those of maltose, and swing the molecules of this substance beyond their sphere of action and dissociate them. The nascent atoms thus set free and forced to recombine under the dissociating wave energy of maltase, find the combining line that leads to glucose—an antibody, the one of least resistance, and as the wave periods of antibody do not coincide with, but may be opposite to, those of maltase, the former will neutralize the latter, more and more as it accumulates (concentrates), until finally the waves of one side will equalize in energy those of the other side. An equilibrium will then be established and the reaction will stop.

Now when glucose—the antibody—is added in excess of that required to establish an equilibrium of forces it becomes a question, What influence will the energy represented by the excess of glucose have upon the other bodies of the reaction? As we have seen, the wave periods of maltase and maltose coincide with each other but are opposite in crest and trough to those of glucose. It seems quite probable, therefore, that the free energy of the latter—that is, the energy in excess of that required to neutralize the energy of maltase and maltose, will fall upon the molecules of these substances, and while it cannot dissociate them it may bring about a rearrangement of the atoms in the molecules, at least in those of the weaker substance—maltose; that is, convert maltose into isomaltose.

Frenkel[16] describes how injurious influences of many kinds applied within limits a little less than deadly will "attentuate" many varieties of bacteria—ferment, chromogenic, and pathogenic; that is, will gradually weaken more and more, and may finally destroy the specific catalytic properties they possess, without ajparently harming the vegetative functions. The attenuated bacteria do not apparently differ from those not attenuated in any respect except in a partial or total loss of power to produce the substance—ferment, chromogenic or pathogenic—they produced under normal conditions. This loss of functional power may be permanent and may be transmitted from parent to offspring through many generations, or the power may be restored by growing the attenuated bacteria under favorable environmental conditions.

Now the most rational explanation of this phenomenon is that the harmful agent weakens or destroys the specific catalytic function of the bacteria by changing the arrangement in space of atoms in the molecules which determine their catalytic power. If this is the case, it furnishes evidence that the harmful action of antibody may bring about similar changes in the molecules of the substrate; that is, transform them into isomers, which make them specifically immune. This explanation of reversible reactions has been much strengthened by experimental work of Bietzka and Neuberg[18] who showed that on subcutaneous injections of emulsion into a rabbit, antiemulsion was formed, and that this body was able to synthesize a disaccharide from glucose. Also by the views of Euhler[19] based upon the strength of this experimental work, who assumes that antibodies in general are the synthesizing enzymes of reverse reactions.

In conclusion I can truthfully say, and without

undue egoism, that many phenomena of enzyme and pathogenic reactions whose existence has only been generally recognized in recent years, as for example, specificity, structure relations, reversibility, and incompleteness of hydrolysis, are legitimate deductions of the principles on which are constructed the catalytic theory of immunity; and as such were described by the author[21] three years before the announcement by E. Fischer[5] of the structural relations of enzymes, and six years before the announcement by Croft Hill[15] of the first definite proof of a synthetic process taking place as a result of a reversible enzyme reaction.

EMPYEMA OF THE ANTRUM OF HIGHMORE: ITS RELATION TO OTHER DISEASES, AND ITS TREATMENT.*

By WOLFF FREUDENTHAL, M.D.,

NEW YORK.

HONORARY PRESIDENT, SECTION ON LARYNGOLOGY OF THE SIXTEENTH INTERNATIONAL MEDICAL CONGRESS AT BUDAPEST, CORRESPONDING FELLOW LARYNGOLOGICAL SOCIETY OF BERLIN (GERMANY).

When one surveys the vast literature of diseases of the antrum it might appear at first sight that the whole subject had been thoroughly covered and that it constitutes a closed chapter in rhinology. Yet one can easily seen how comparatively recent is our knowledge of empyema of that cavity when one remembers, for instance, that Voltolini did not even mention it in his text-book on Diseases of the Nose, which appeared in 1888. It was Voltolini, however, who by his method of transillumination has done so much toward furthering our knowledge of this affection. This method he described in an appendix to his book, and quotes a case which had been diagnosed as sarcoma, but which he afterward found to be nothing but an empyema. It must be said, however, that Ziem, a few years previously (in 1886) had drawn attention to the frequent occurrence of empyema. It was Zuckerkandl who first thoroughly studied the anatomy of the pneumatic cavities. He advanced our knowledge considerably, and his fundamental work was not only then, but is to-day, the basis of all our study and progress in the field of rhinology. It is far from my intention to enter into the details of the development of this new field of rhinology, and I prefer to plunge directly into my theme. In order to understand the relation of empyema of the maxillary sinus to other diseases we must first discuss its etiology.

*Read before the German Medical Society of the City of New York, May 3, 1909.

The first etiological factor to be considered is the teeth. There is a considerable number of persons in whom the teeth (especially the first and second molar) protrude into the antrum. The osseous part of the cavity is sometimes so thin that it breaks easily when a tooth is extracted, thus opening the maxillary sinus. That an acute empyema may develop in such a way we all know. It is only surprising that infection does not more frequently occur in this manner, since to a large number of dentists such precautions as sterilization of instruments, or asepsis and antisepsis seem to be entirely unknown—at least one notices very few signs of them in their work. Of course, an infection may ensue in spite of the greatest care, but I have seen too many cases in which the dentist was not free from all responsibility. It is fortunate that the majority of such infections improve rapidly with or without our aid. But a case like the following ought to be a warning to all:

E. B., a poorly nourished child, six years old, had suffered from toothache seven days before admission to the hospital. A tooth was extracted two days later, and very soon afterward the face commenced to swell. Pus was discharged from the socket, the face became painful, and continued to swell more and more, together with the lips and the eye on the affected (left) side. Fever.

On admission, the child was stuporous; strong fœtor ex ore; marked swelling of the face, which now extended even to the right side, so that both eyes were closed. Large amount of purulent discharge. Temperature, 104.2° F; pulse, 180; respiration, 48. Leucocytes, 19,000; polynuclears, 83 per cent.

On account of the gravity of the case, operation was performed immediately. The left antrum was opened through the canine fossa, and a mass of necrosed tissue was removed. Then an opening was made into the alveolar process through the socket of the second bicuspid, and drainage tubes inserted. The nose was apparently free.

During the next few days the temperature ranged between 102 and 105° F., the pulse was 150-180, respiration 36 to 44; the general condition grew worse constantly, and finally nourishment was refused. To reduce the very pronounced cellulitis, several incisions were made, but no pus was found. Death occurred from septicemia three days after the operation.

The report of a physician who happened to be present at the extraction of the tooth, and who afterward saw the child in the hospital, leaves hardly any doubt that the infection was to be attributed to the carelessness of the dentist.

As a matter of curiosity, the following case may be added here: A young lady of the better classes, whose family I have been treating for twenty years, asked me to consult with her doctor, as is the cus-

tom in this family whenever anything serious occurs. I found the patient in a very excited condition; she could not sit up in bed, felt dizzy at the slightest motion, and had just had a chill. Her temperature was 104° F. The doctor had made the diagnosis of pleurisy, but I was unable to find any trace of that condition, nor was I able to find any cause for the high fever. Finally, I thought that as a laryngologist I should look at the pharynx, although the patient did not complain of it at all. To my surprise, I found in the socket of a tooth a thread, and upon pulling it out a strip of gauze followed, giving vent to an extremely foul odor and to a quantity of thick pus from the antrum. I learned then that the patient had had a tooth extracted twelve days previously, and that on account of severe hemorrhage a tampon had been inserted. The young lady had forgotten the matter entirely until I drew her attention to it. She recovered in a few days.

Much more frequently, however, dental caries perforates the bone and penetrates the cavity of the antrum. In fact, in the early period of our surgical work in the field of rhinology we seldom did much more than drill a hole through the alveolar process and syringe the antrum. At that time it was the belief that the majority of the cases of empyema were caused by disease of the teeth. As so often happens, this view has undergone complete change. In view of the good results now attained with the major operations, one is apt to forget completely the possible dental origin of many cases of empyema. For some years I have not drilled through the alveolar process to reach an antrum for therapeutic purposes, yet I should like to sound a note of warning that we should not forget one cause of this disease, *i. e.* a carious tooth, while planning an elaborate operation.

On the other hand, it cannot be denied that the majority of cases of empyema of the antrum have their origin in the nose. Think of the intimate connection of the nasal mucosa with that of the antrum, remember the position of the natural and accessory ostia, and you will easily understand how a mucocele, hydrocele, and finally an empyema, may develop when these are closed for some time.

Now, given a case of empyema of long duration, frequently the reverse happens, namely, that as the result of the long stagnation of the exudate in the antrum, the teeth which protrude sometimes into the antrum become affected and their integrity is endangered. Therefore it may be correct to say that in some cases of empyema of the antrum the aid of the rhinologist is required; in others that of the dentist.

There are other diseases with which empyema of the maxillary sinus is often directly connected. One of these is

Aprosexia Nasalis.—As a characteristic example of this affection, which hitherto has been mentioned only in connection with adenoids, the following case may be cited:

Miss A. G. was referred to me by Dr. Einhorn on January 18, 1908. She complained of discharge from the nose, and headache, from which she has suffered for more than a year; besides, there was constant feeling of pressure in the center of the forehead. She has been very nervous since childhood, is still suffering from chorea, and gives the impression of being stupid. There were polypi in the right nasal chamber, after the removal of which an empyema of the maxillary sinus was found.

I performed a radical operation, employing the Caldwell-Luc method, and the patient recovered in a comparatively short time. At present, a year later, the impression she makes is entirely different —not only does she appear more intelligent, but she is brighter mentally. Without my questioning her, she tells me that her memory has improved remarkably. She helps in her father's business, and now knows—so she informed me—not only the names of the customers but also their wishes. The result of the operation is satisfactory in every respect.

The power to concentrate thoughts is lost in many of these patients, and this not only in children or young people but also in persons of advanced years. Thus, I operated a few months ago on a plumber 47 years of age, who had been suffering from headaches for the past ten years. For nine months he had been troubled with a constant dull pressure in his head. He is, as he expressed it himself, "in a constant stupor," and feels "as if he would rather not think of anything." This very intelligent patient told me that he could not do his work any more, and could only direct his employees.

There are a great many such patients, and we can find them if we only take the trouble to look for them.

Other diseases to be considered are:

Affections of the Stomach and Intestines.—The following is a case of great interest:

Mr. H. J. U., 65 years of age, merchant. Last summer I had occasion to see him very frequently, as he and I traveled daily on the same morning train from the country to the city. Only too often he told me of the "trouble he had with his stomach and bowels," trouble which would not let him sleep more than a few hours at a time. Finally, on September 14, 1908, he came to my office with a swollen face, and I learned that he had been suffering from pain in the region of the left antrum for several days. These pains now extended upward to the left frontal sinus. Upon questioning him, I ascertained that for many years he had had a purulent discharge from the nose, for which he had been treated as far back as 1890. The left maxillary sinus was swollen anteriorly and over the alveolar process, very painful on pressure, and fluctuating. Temperature, 100.5° F. It was evident that there was here an acute exacerbation of an old empyema of the antrum. On the following day Denker's operation was performed. The anesthetic was poorly taken. Within a few months the patient became perfectly well, and on March 1, 1909, he told me that he has had no trouble with his digestive tract since the operation. The pain in the stomach which had annoyed him so much has entirely disappeared.

The relation of these digestive disturbances to the empyema of the antrum is easy to understand. The pus that collects in the antrum overflows during the night, that is, it passes through the ostium maxillare into the pharynx, the esophagus, and finally into the stomach, where it gives rise to distressing gastric symptoms.

The following history also tends to show how some patients are treated for many years for gastric conditions without attention being drawn to the true cause of their ailment:

Mr. M. B., 43 years of age, merchant, has suffered from colds and nasal catarrhs as far back as he can remember. He has also been a victim of chorea and other nervous disturbances. For example, he could not remain for any length of time

in a crowded place because he was always liable to faint under these conditions. For this reason he could not obtain a commerical position, and decided to emigrate to America. For ten years he had lived in Colorado, where he was constantly troubled with indigestion, nasal catarrh, headaches, and dizziness. At times these symptoms were so intense that he feared he would become insane. Twice he fell down in the street in a fainting fit.

Although he had consulted a number of prominent physicians, his condition had not improved, and he finally returned to his home in Koenigsberg in Germany, where Prof. Schreiber was the first to recognize the true condition. He referred him to a rhinologist, who opened up both antra through the alveolar process (in 1897), and the patient returned to Colorado. His headaches, however, continued to be as severe as before, so that Dr. Robert Levy, of Denver, Col., had to open the right antrum again in 1898. Even this was of no avail, and a half year later he again returned to Germany where the radical operation was performed on all the accessory sinuses of the nose. Great relief followed, and the patient soon returned to his business in Colorado. But unfortunately the old symptoms reappeared and the patient suffered greatly during the following eight years.

When I first saw him on March 3, 1906, he complained of excruciating headaches, profuse discharge from the nose, loss of appetite, etc. In each antrum there was still a plug. When I removed the one on the right side, the pus simply flowed out; the same occurred on the left side, and also when the patient was told to bend over a little. I have never seen so profuse a discharge of pus as in this case. A large polypoid mass was removed from the right side, and all the accessory sinuses were irrigated. The latter procedure had to be repeated every morning, and the patient himself had to perform the irrigation of the antra once or twice a day, so marked was the secretion. During the following two weeks I curetted the accessory sinuses as far as I could reach them, opened the right sphenoidal sinus, and the patient felt somewhat easier. I considered a radical operation of all the accessory sinuses the only salvation for him, but the patient did not care to submit to such an operation, preferring to take the chances, and went back to Colorado.

On September 1, 1906, he returned to New York, and I continued treatment along the same line. He took sea baths, which agreed very well with him, and returned to Colorado two weeks later. After half a year he again came to New York, and a radical operation was performed on the right maxillary sinus. After that he returned to Colorado much improved. A few days ago he again reported in a very good condition. I had taught him to syringe his frontal and maxillary sinuses himself, and he has done this so effectively that to-day the left side may be considered cured. There is still a small opening in the left antrum, but no discharge of pus whatsoever. On the right side there is some secretion from the frontal sinus, but more from the maxillary sinus. The quantity, however, is small, so that now the patient can let a few days pass before syringing that side. It seems that at present the antrum is only the reservoir for the pus coming from the frontal sinus. The patient looks and feels very well.

We can see in his instance how much can be achieved sometimes by a rather conservative treatment, yet I must confess that in other cases I would proceed just as I did here—that is, I would not take chances in allowing a man to travel several thousand miles with such an alarming discharge from the frontal and other sinuses. I should therefore advise a radical operation in other similar cases.

Some interesting points concerning this case were revealed by a radiograph of the accessory sinuses. Although the left maxillary sinus may be considered cured, clinically, it appears darker on the plate than the right. The ethmoidal cells appear of the same shade on both sides. The most interesting point, however, is that each frontal sinus appears to be separated by a *horizontal* plate into an upper and a lower cavity. As one can see in the radiograph, the lower part of the right frontal sinus is the only one that is absolutely clear, *i. e.* is draining well. Whatever there may be in the other parts of these cavities cannot be surmised. It seems strange that at the operation by Kuhnt's method the horizontal plate should have remained undiscovered. A colleague who saw the patient suggested that that plate was probably taken to be the floor of the frontal sinus at the time of the operation. However this may be, this case is one of the most interesting that I have seen in years.

In the next section of my paper, I come to a subject that is somewhat more difficult to explain, namely, the relation of antral empyema with

Epilepsy.—It is now probably a generally accepted principle that in this disease all peripheral irritations must be removed, as, for example, affections of the eye, ear, nose, or other organs. Furthermore, it seems to be an established fact than an operation on any part of the body frequently exerts a very beneficial effect on epileptic attacks. It is therefore not surprising to find that good results also follow operations on the nose in these cases. Thus, I distinctly recollect a patient whom I treated many years ago, who was suffering from epilepsy, and in addition had an empyema of the maxillary sinus. I made an opening through the alveolar process, and directed him to syringe his nose for months, as was customary at that time. During that period his epileptic attacks, which had previously occurred every eight to fourteen days, did not reappear. The patient, however, removed to another city, so that I cannot report anything further about him.

Another case was referred to me on June 4, 1908. This patient was the daughter of a colleague, and was 25 years of age. She had suffered for years from epileptic attacks which occurred every six to eight weeks. The father noticed that her nose was obstructed, that there was an occasional purulent discharge from it, and that she complained of headaches on the left side. An empyema of the left maxillary sinus was found, and was operated upon the next day by Denker's method. Two weeks later when the patient returned for the first time to my office, she had a typical epileptic attack that lasted for eight minutes. There were present foam at the mouth, livid discoloration of the lips and face, unconsciousness, biting of the tongue, etc. A few days later she returned home, where her father continued the treatment. Up to date, ten months have elapsed and she has not had another attack. It cannot, of course, be said positively that she will remain well.

In several other cases of epilepsy I have had similar good results, but I must also confess that I have had some in which no improvement followed the operation.

Tuberculosis.—Wertheim found that almost one-third of patients who had died of tuberculosis had an empyema of one or more of the accessory sinuses. E. Fraenkel also observed a large number similarly affected. I have for many years devoted a great deal of attention to the occurrence of empyemas in tuberculous patients, and it is my firm belief that Wertheim's numbers are too small. Tuberculous affection of the maxillary or any other sinus is very rare, but pyogenetic affections are the most common of all.

Eye Diseases.—The connection of the maxillary sinus with affections of the eyes forms a very important chapter, which is, however, too large to be discussed here. The involvement of the ethmoidal cells ought to be included in this discussion, which however lies beyond the limits of our theme tonight.

Diagnosis.—Before speaking of the operative procedures, we must discuss briefly the diagnosis.

When we began to study the accessory cavities, it was the transillumination method of Voltolini that attracted great attention. It is a peculiar coincidence that almost twenty years ago I had a chance to demonstrate that method for the first time in America before the Section on Laryngology of the New York Academy of Medicine.* I take great pleasure in passing around the instruments which I received at that time from Professor Voltolini.

Since then this method has been tried all over the world, and we can say to-day that it is but one of the methods which, in some cases, aid us in making a diagnosis of empyema. More cannot be said of it.

In some instances we succeed (especially after putting the patient in the Frænkel position) rhinoscopically in seeing pus oozing from the hiatus semilunaris. If this pus always returns after having been wiped away, or even if it shows pulsation, the diagnosis is rendered much more probable. The most important and safest method is to enter the antrum with the aid of a small needle and to evacuate the pus. This method was first recommended by Zuckerkandl, and then tried by Moritz Schmidt, Lichtwitz, Hajek, and others. Personally, I prefer the instrument recommended by Beaman Douglass. It has been said of this method that it makes a wound, that it "stirs up" the normal conditions of the antrum and creates pathological ones. That may be true if one uses a very thick trocar, but if one employs the instrument of Lichtwitz, or one of its modifications, the whole manipulation is not more serious than a hypodermic injection. Among the hundreds of punctures that I have made—of course under thorough cocainization—I have never encountered any that presented the slightest difficulty. Several times, however, I failed to perforate the antral wall, and I cannot say what was the cause of these failures—possibly thickened bone?

An important advance in the methods of diagnosis of empyema was made by the discovery of the Roentgen rays. Though an empyema of the antrum can ordinarily be diagnosticated with comparative ease, yet there are cases in which the Roentgen pictures are of great value. First, they show the extent of the cavity, a point which, of course, is of greater importance for the frontal sinus. Second, there are cases in which after repeated puncture no pus can be found, yet there is an empyema present which can be demonstrated by the skiagram. These, however, are the exceptions. Generally speaking, we may say that we can rely to a certain extent upon the Roentgen picture in cases in which the conditions are not otherwise clear; but to make the operative procedure depend upon the findings of the skiagram in every instance would be just as wrong as to rely solely upon transillumination. In Germany, where many rhinologists have occupied themselves with practical skiagraphy, they have reached very similar conclusions. Not only is it an art to take such pictures well, but it is also difficult to interpret them—and here the imagination of the interpreter plays a very important rôle.

Permit me to show you a few pictures* which may be of interest.

Mrs. L. Transillumination showed shadows over both antra. The skiagram, however, reveals plainly that the affection is on the right side only, where the other sinuses are also affected. These findings are especially important, as the patient constantly complained of pain over the left eye. We were not able clinically to find any evidence of disease on that side.

William A. G. This case is instructive because it demonstrates how easily mistakes can be made if one makes a diagnosis solely from a Roentgen picture. The patient consulted me a year ago on account of chronic empyema of the left antrum. He showed clearly a projection of the antrum toward the mouth, so that a general surgeon intended to operate upon him from the mouth. I performed a Denker's operation, and the patient got well. When he returned to me for other reasons, I had the Roentgen picture made. A radiographer, who knew nothing of the patient's history, writes me: "The plates show a lesion of the maxillary sinus on the left side. Although not at present filled with pus, it does not have the clear cut and well-defined outline of a normal sinus, as is shown on the opposite side." The latter is perfectly correct, and the cause of it is that in consequence of the operation a thickening of the bone has occurred that makes the sinus appear indistinct, though no empyema is present.

Mr. M. B., from Colorado. This case has been discussed above.

Miss A. G. Transillumination and skiagram give identical results, namely, empyema of the right maxillary sinus.

Miss R. S. was operated upon three months ago for bilateral empyema of the antrum. After the operation the cavities were packed with iodoform gauze. At the time of the first dressing the gauze was torn and a piece was left unnoticed in the right maxillary sinus. A week later, when I saw the patient, the piece of gauze, that had caused a horrible odor and a reinfection of the antrum, was discovered. The picture shows this empyema distinctly.

Mrs. P. S. Empyema of the right maxillary sinus. The frontal sinuses cannot be seen. Whether they are entirely absent, or are very small, or are filled with pus, cannot be decided. The patient did not return for further treatment.

Treatment.—The acute cases of empyema of the maxillary sinus are best treated according to general rules, without operative interference. If possible, the antrum should be syringed with hot saline solution through the natural ostium. Occasionally, however, it is easier to puncture the antrum and then to syringe. This may be required several times. If after a time the condition does not improve it is advisable to make a small opening at the place of puncture, and to irrigate the antrum daily through this

*Medical Record, May 17, 1890.

*The pictures were exhibited, but are not reproduced here.

aperture. In a large number of cases of acute empyema the above simple methods are sufficient for a cure. In other cases, however, the process becomes chronic. Some patients declare that at the slightest provocation they have a recurrence. This is nothing else but an exacerbation of a so-called latent empyema.

How, then, should we treat a chronic empyema of the antrum? As far back as 1889 Krause recommended the opening of the maxillary sinus through the lateral nasal wall by means of a thick trocar. L. Réthi, in 1901, made a broad opening in that wall, after first removing two-thirds of the lower turbinate. This method is frequently employed to this day, and with some modifications was highly recommended by men like Claoué, Myles, Richards, of Fall River, and many others. In certain cases that are comparatively slight, I also employ this method. Where, however, a deep degeneration of the mucosa or the bony septa is diagnosed or suspected, there is only one method, *i.e.* the radical operation through the canine fossa. This is the only method by which we can successfully cope with these conditions.

But, let us hear what the advocates of the "Intranasal method at any price" have to say: First, it is asserted that the intranasal operation can be done under cocaine, which surely is a great advantage over general narcosis, but whether this, as well as the absence of any severe hemorrhage, and finally the shortening of the whole procedure, outweighs all the disadvantages of the method is a serious question. I have seen severe hemorrhage after the removal of one part of the inferior turbinate; others have had the same experience. Furthermore, Dr. Richards, of Fall River, a very careful observer and supporter of the intranasal method, says that if the condition should not improve "after a reasonable length of time," the radical operation should then be done. If this be the case, I would propose to do the latter at once, for the former is an extremely unpleasant procedure for many patients. At present we have reached a point where "each writer has vied with his confrères in destroying as much as possible of the nasal wall of this cavity, and it is remarkable what ingenuity is displayed in devising new chisels, saws, drills, etc., for this purpose" (T. W. Moore).

But there is another important reason why I am not inclined to make a large opening in the lateral nasal wall, and this experience has taught me:* I have seen several cases that have been operated upon by good men and *lege artis*. There was not much left of the inferior turbinate body after one or two-thirds of it had been cut away, and the remainder had atrophied markedly. The lateral wall had been resected so far that antrum and nose now formed an extraordinarily large cavity. What happened then? At the slightest change of weather a profuse discharge occurred, and the patients felt just as miserable as before. The protection that the normal turbinate and the rest of the mucosa give had been taken away, and the sensitive mucosa of the antrum, which is not made for direct respiration, reacted in a very unpleasant manner upon every change of temperature, dust, etc. (B. Kyle).

Certainly we must remove as thoroughly as possible all the diseased parts, but let us leave intact the normal structures, so far as we can.

Another point should not be neglected, that is, the position of the floor of the antrum in its relation to the floor of the nose (John O. Roe). What we want to accomplish in all these operations is perfect drainage, and that is naturally impossible when the floor of the antrum lies lower than that of the inferior meatus. In such cases one can make ever so large an opening into the lateral nasal wall, yet the antrum will never drain thoroughly and the pus will never cease to form. Here, too, we are forced to perform that operation which is the most conservative, namely, the radical operation.

In this operation, as is well known, the larger part of the anterior wall of the antrum is chiseled away so that one can easily examine every part of the sinus. The removal of this bone does not affect the patient very much, firstly, since we strive for obliteration of the sinus; and, secondly, because we can leave such portions of the antral mucosa as are found normal. Naturally, a counter-opening must be made into the nose, but I make this as small as convenient. If it afterwards closes up entirely there is no harm done, provided the process has healed in the meantime. If not, the perforation can easily be kept open.

Of the accidents that occur in these operations, the following may be mentioned: That serious hemorrhages may occur when the anterior wall is opened, so that the operation has to be abandoned entirely, is well known. Such an accident occurred in three cases among several hundred upon which I have operated during the last twenty years. For the past three years this accident has not occurred at all in my work (Coincidence?). The operation can generally be completed after an interval of twenty-four hours in these cases.

A severe syncope with profuse secondary hemorrhage occurred in the following case: Miss S. H., 19 years old, has suffered from headaches on the right side for the past six months. There was pain over the right maxillary sinus. On admission to the hospital there was a temperature of 104° F.; pulse 108, respiration 30. Denker's operation was performed, with my slight modification. Everything went smoothly, excepting that there was some slight bleeding when the nasal mucosa was lifted from the floor of the nose. This, however, stopped after a little while under the use of packing and adrenalin. Half an hour after the patient had been removed to her bed, the house surgeon called me to her on account of uncontrollable hemorrhage. She had vomited large masses of blood, and blood apparently still ran down into the pharynx. The pulse could not be felt. An intravenous infusion was given immediately, the nose packed tightly, and ice applications were made. It was not until two hours later that her condition was such that I could venture to leave the hospital. After that she twice collapsed again, and the hemorrhage only ceased after another six hours. The patient recovered and left the hospital sixteen days later.

In some of my cases toothache persisted for several weeks after the operation, and in others pain in the face. In still another series of cases the face remained swollen for several months after operation.

Occasionally I saw in the antrum such numerous granulations—or, as Hajek prefers to call them, "hypertrophies of the mucosa"—that they gave the impression of a malignant neoplasm, but microscopical examination showed,—with one exception,—that this was not the case. The exception occurred in a young man of twenty who was sent to the hospital with a diagnosis of sinusitis maxillaris. At the operation the anterior wall was found to be as thin as paper, so that one could penetrate into the antrum

*Braden Kyle has reported a similar experience.

with a scalpel. A mass of granulation tissue was curetted out that afterwards proved to be a giant-celled sarcoma. The history showed that the patient had been struck in the face with a ball and that the disease had since developed. At least the patient dates his suffering from that time. When I presented this patient at the Section on Laryngology of the New York Academy of Medicine, two cases were reported by Dr. Harmon Smith in which a sarcoma had developed after a trauma. These, however, concerned a horse and an ox.

In the presence of malignant changes in the mucosa, its complete removal, etc., is naturally imperative. In benign cases, however, such a radical curettage of the entire mucosa is not indicated and is not advisable for the cure of the disease. The more of the mucosa one can leave *in situ*, the more rapidly a cure is effected.

These principles were followed by me in the Caldwell-Luc operation and in Denker's modification of it. The latter I have performed twenty-nine times, with the modification mentioned above. Wherever it was possible I left the inferior turbinate intact. This is preferable in all cases where the anatomical condition is such that a satisfactory opening into the lateral wall of the nose can be made. In others, in which the inferior turbinate occupies the largest part of the inferior meatus, one must remove part of it.

The isolated empyemas of the antrum which have been discussed here are not the most frequent. More often they are associated with affections of the ethmoidal labyrinth, or the sphenoidal or frontal sinuses. Some authors go so far as to declare that in every case all the accessory sinuses of one or both sides are affected. It would be unfortunate if such a theory were found to be valid in practice. The number of cases of isolated empyema of the antrum which have been cured is too large to be ignored.

1003 Madison Avenue.

FURTHER OBSERVATIONS UPON RIGIDITY OF THE CHEST MUSCLES AS A SIGN OF INVOLVEMENT OF THE PULMONARY PARENCHYMA.*

By F. M. POTTENGER, A.M., M.D., LL.D.,

MONROVIA, CALIFORNIA.

In describing this new physical sign in the *Journal of the American Medical Association*, March 6, 1909, I said that it "consists of a rigidity of the muscles of the chest wall, particularly of the intercostals. By making gentle pressure with the tips of the fingers over the intercostal space the experienced touch will detect a resistance on the part of the muscles that overlie the inflamed parts which is like that noted in the muscles of the right lower quadrant of the abdomen in appendicitis, in the right hypochondrium in hepatic colic or the general rigidity of the abdominal muscles when general peritonitis is present."

As to the frequency of the sign, I stated in my paper in the *American Journal of the Medical Sciences*, May, 1909, that "in the examination of patients suffering from pulmonary tuberculosis, I have found this muscle rigidity, particularly as it affects the intercostal muscles, to be a constant sign. Not only have I been able to map out the areas of infection, but I have been able to judge the nature of the infiltration with a considerable degree of accuracy by the condition of the muscles, the rigidity being much greater over dense infiltrations than over infiltrations of lesser degree, and greater over recent inflammatory filtrations than over old, quiescent ones."

More extensive experience confirms the above statements, and I now find this sign to be one which furnishes very important data in the examination of patients suffering from pulmonary tuberculosis. While we have been led to believe that palpation is of little value in the diagnosis of pulmonary lesions, with the recognition of this new sign we are compelled to assign to it a place of at least equal importance with percussion, and of greater importance in one respect, viz., it gives us information as to the acuteness of the process. In my former communications I was inclined to place reliance on the rigidity of the intercostal muscles almost to the exclusion of that noted in the more superficial groups. Further experience would indicate that in this I was in error and that the superficial muscles also show this rigidity to a marked degree. For example, at times in picking up the mass of muscles covering the apices of the lungs and comparing the two, the difference is at once apparent, the muscles of the affected side appearing more rigid than those on the other. Care must be exercised to exclude the natural difference in favor of the muscles used most; but a little practice will enable one to do this without difficulty. A very important aid is furnished by palpating deeply and noting the condition of the deep muscles. It was in the deep muscles of the supraclavicular region, those covering the apex, where about a year ago I first noticed this sign, but being unable to convince others of its existence, I thought that I might be mistaken; so it was not until I had noticed it in the other chest muscles that I described it.

It is a well-recognized fact that rigidity of the muscles is confined to those groups directly overlying the foci of the disease, yet the explanation of this fact does not seem entirely clear. The explanation of the cause of this muscular spasm being an underlying pleuritis suggests itself, but does not account for it fully. Quoting from my former paper (*American Journal of the Medical Sciences*, May, 1909): "The analogy of the abdominal conditions which are accompanied by muscle rigidity also speaks against the involvement of the underlying pleura as a necessary cause of the rigidity. In appendicitis the rigidity of the abdominal muscles is present when the inflammation is confined to the organ itself and the parietal peritoneum is free from disease. The same is true in gall-bladder disease and pancreatitis, so it would seem that inflammation of a contiguous part is not necessary to produce these muscular spasms."

In examining for muscle rigidity, I would suggest that both the superficial and deep muscles be palpated, the superficial with light and medium pressure, and the intercostals with firm pressure.

This muscular rigidity is detected with various degrees of ease in different individuals and in the same individual under different circumstances. It is the easiest to detect in individuals who do not have too much subcutaneous tissue, and whose muscles are normally not too firm; however, a fair muscular covering of the chest wall seems to be advantageous, because under these circumstances the underlying bones do not interfere. The acuteness of the process in the lung affects the amount

*Read before the American Climatological Association, Old Point Comfort, Va., June 4 and 5, 1909.

of rigidity; thus, when the process is active the sign is more pronounced than when the acuteness has passed away. In this way, at times when both lungs are involved, or when different portions of the same lung, it may be judged on which side or in which portion of the lung the process is more active.

In acute inflammations this rigidity must be due to a stimulation of the nerves which results in a tonic contraction of the muscular tissue, but this can not be the case where the rigidity has remained for months and years, as it does in chronic cases. According to our knowledge of the laws of physiology it would be impossible for a muscle to remain in a constant state of contraction. Sooner or later it would lose its power to contract and relaxation would ensue. It seems to me, then, that we must, from a theoretical standpoint, assume that certain pathological changes occur in the muscles which result in a more dense consistency; and, that rigidity, which shows itself for months and even years, is not due to muscular contraction so much as it is due to these pathological changes.

Specimens of muscle which were the seat of this chronic rigidity were subjected to microscopical examination to ascertain the exact changes which had taken place. The following is the pathologist's report, although based on too few specimens to be final:

"In the muscle specimens I find fibers which have undergone hyaline change. The substance of the fiber is replaced by a homogeneous substance. In one specimen this was broken up into irregular masses such as we find in so-called waxy degeneration of the muscle. In all these hyaline areas there were apparently between the replaced fibers extremely long, delicate nuclei. As near as I could make out these were the nuclei of endothelial cells of either the blood or lymph capillaries."

While the practical value of rigidity of the chest muscles as a diagnostic sign in diseases of the pulmonary parenchyma is of first importance, much interest is also attached to it because of the relation which this rigidity bears to other well-known signs. Muscle rigidity is undoubtedly an important factor in the causation of "lagging," "diminished motion," "contraction," "impeded or diminished respiratory murmur," and "ankylosis of the costosternal articulation of the first rib and the resultant phthisical habitus," concerning which so much has been written. It is also possible that the sounds heard on auscultation may be somewhat influenced by the condition of the muscles, for muscle contraction enters into the makeup of what is termed the respiratory murmur to a surprisingly great extent, as was demonstrated to me by my friend, Dr. D. J. McCarthy of Philadelphia, on a patient whose chest muscles were paralyzed. The muscular element in the respiratory murmur may also be demonstrated by listening over the collapsed lung in pneumothorax, or by placing the stethoscope over some muscle as the biceps during its contraction. The more rigid walls produced by the muscular spasm of necessity alter the percussion note to some extent, although we may not be able to appreciate it.

In my previous paper I discussed the effect of muscle rigidity on some of the more important symptoms, but I now wish to discuss this more fully.

Lagging has been looked upon as a very important symptoms in apical infections. It shows itself early, being often detected when the changes on percussion and auscultation are so slight that they can barely be recognized. Lagging often calls my attention to an apical disease, and I have learned to look for it as one of the first signs in examining a chest for early tuberculosis. The cause of this lagging has long interested me and I had looked upon it as being due to an interference with the normal elasticity of the lung tissue as a result of which the apex failed to expand fully. While this may partly account for it, yet it seems to me now that we have a greater factor in the spasm of the muscles which results from the inflammatory change in the lung. This spasm limits the movements of the upper rib or ribs and consequently causes a lagging of the affected side.

The muscles which show spasm are those immediately over the focus of infection. When it is at one of the apices those immediately covering the apex become rigid first, and then as the disease extends lower down the intercostals and superficial chest muscles take upon themselves a state of tonic contraction. Whether or not the superficial muscles show contraction at once upon the presence of inflammation, I do not know, but I have been able to detect it in all of the early cases which I have examined. When these muscles covering an apex contract, the result is a degree of fixation of the upper ribs resulting in limitation of motion, which is commonly perceived and described as lagging.

Diminished Motion.—This may be considered as being identical with lagging, but this term is usually applied only when a greater amount of the lung has become involved. While there are doubtless several factors entering into the causation of this sign at different times, yet I do not doubt that often the immediate cause is at first the tonic contraction of the chest muscles, later the pathological thickening of the same, as we find it in all advanced, long-standing cases.

Contraction.—We have been wont to look upon contraction as being due to the chest wall falling in, or being drawn in, so to speak, to take the place of tissue which has been destroyed, but it is probable that the muscle change which produces lagging and later diminished motion of a great portion of the lung would also probably be the most potent factor in drawing the chest wall inwards, resulting in the contractions so often met with.

Impeded or Diminished Respiratory Murmur.—The part played by muscle spasm in the production of this sign is very evident, for the fixation of the upper ribs and the resultant limited motion cannot fail to impede the entrance of air to the apex and cause a diminished respiratory murmur. This sign, which I personally regard as one of the most important signs of early tuberculosis heard on auscultation, conveys to the ear of the examiner the impression that the air, in entering the lung, is doing so against obstacles.

Ankylosis of the Costosternal Articulation.—This sign or condition was described by Freund in 1859 ("Beitraege zur Histologie der Rippenknorpel im normalen u. pathologischen Zustände"), but received little attention until recently, when it was again brought forward by its author ("Thoraxanomolien als Prädisposition zu Lungenphthise u. Emphysem; *Verhandl. der Berl. med. Gesellschaft.* 27 Nov. 1901) and was confirmed by Schmorl ("Zur Frage der beginnenden Lungentuberkulose," *Muench. med. Wochenschrift.* 1901, Nr. 50.), and by Hart ("Die mechanische Disposition der Lungenspitzen zur tuberkulosen Phthise," 1906.) and others.

Ankylosis of the costosternal articulation of the first rib is considered by these men as being a mechanical predisposing cause of tuberculosis, in that it interferes with the motion and consequently with the flow of blood and lymph through the apex, thus mechanically predisposing the apex to infection. It would seem probable in the light of our observations on muscular spasm that ankylosis of the first rib is a result of muscle spasm which is dependent upon a tuberculous focus already present in the lung rather than a predisposing factor in its causation. That a pathological condition is present in the muscles surrounding the ankylosed costosternal articulation was recognized by Freund, but, as was natural, he attributed it to the action of the muscles in their attempt to move the ankylosed rib.

The inspiratory motion of the first rib is upward and outward, and with this action the upper aperture of the thorax is enlarged. The upper edge of the rib is drawn backward, the under surface outward and the flat surface of the rib assumes an almost horizontal position. This change of position requires considerable motion between the first costal cartilage and the sternum, as mention by Hart (*loc cit.*), and when it was noticed that the costosternal angle was ankylosed and that the muscles attached to the first rib and whose function it is to elevate it were in a condition of pathological thickening, it was perfectly natural for Freund and his followers to account for this as an hypertrophy caused by overwork on account of the muscles being compelled to pull against the unyielding rib, held firm by the ankylosis of its cartilage with the sternum. It seems probable, however, that these observers have taken the cause for the effect. The inflammatory change in the lung causes the spasm of the muscles. This limits the motion of the first rib and has a tendency to fix it at its costosternal articulation. In the muscle at first there is a condition of irritation which results in spasm, but, as the irritating cause remains, the muscle undergoes pathological change which results in chronic thickening. As a consequence of this, the first rib is held more or less firmly fixed and the opportunity for ankylosis is offered. Added to this, we must assume that the same cause which produces the irritation of the muscles and causes them to undergo pathological change has a similar effect upon the perichondrium. Freund noted these changes, but described them as being an ossifying perichondritis due to the pulling and drawing of the overworked muscles.

I have been able to detect muscle rigidity in every case of tuberculosis of the pulmonary form examined by me since I have been using this sign. The degree of rigidity differs in different cases, but I cannot conceive of its absence. I have also found it present in pneumonia, pleurisy and emphysema, and would expect it to be found in all inflammatory conditions of the lungs and pleura.

It promises much for early diagnosis and is of considerable value in helping to differentiate between quiescent and active lesions. If an apex is the seat of a tuberculous focus the muscles at that apex will appear more rigid than at the other apex. If the apex is the seat of an active inflammatory process, the rigidity is much greater than where the focus is quiescent. An observation which I have long made, but one, which seemed so contradictory in the light of the teaching that a retraction of the apex as shown upon percussion is one of the early signs of tuberculosis, that I failed to interpret it, is, that the muscles covering an apex which is the seat of an acute inflammatory process, such as we find in an active tuberculous lesion, often stand out and make that apex appear fuller than the one which is unaffected or which is the seat of an older and less active lesion. Of course, the latter condition was easy to explain because of contraction which had resulted, but the former seemed contradictory; but now it is easy to see that it is due to the muscles covering the apex being in a condition of spasm, thus appearing larger than normal. Valuable information on early apical infections may often be elicited by simply observing or palpating these muscles.

It is impossible for me to go fully into a discussion of this sign as it bears on the diagnosis of diseases of the lungs and pleura in the short time allotted to this paper, but I hope by calling the attention of the active workers of our society to it that they may take it up and develop it for themselves.

THE THERAPEUTIC VALUE OF THE ANTIGONOCOCCIC SERUM AND GONOCOCCIC BACTERINS.*

By GEORGE KNOWLES SWINBURNE, M.D.,

NEW YORK.

My paper will be a short one, based on the clinical experience of the past three years in the classes of cases in which I have found these new therapeutic measures of value.

First, I wish to enter my feeble and probably ineffectual protest against that palpably absurd term vaccines. Inoculation, which has also been suggested, seems to me to be equally objectionable. While vaccine and vaccination should refer only to inoculation with cowpox, by inoculation it seems to me we mean the transference of living organisms to a living animal or human being; thus we may inoculate with smallpox, with syphilis, with gonorrhea. At the same time I must confess my inability to suggest the proper term; it seems to me, however, that the term bacterins (referring to suspension of dead germs) is less open to objection.

In this connection I will relate an experience which occurred at my clinic only within the past two weeks. A young man presented himself with gonorrheal rheumatism of two months' standing, who said he had heard that vaccination was being used as a remedy in gonorrheal rheumatism and he had gone to a doctor and had himself vaccinated and he had derived no benefit from it at all. He exhibited the recent mark on his arm caused by the vaccination. Although this young man belonged to the population of the East Side in New York, he had some idea of the proper use of the English language, if his ideas of medicine were a little mixed.

Taking up the first use of the antigonococcic serum, I wish to refer to its value in gonorrheal rheumatism. In looking over my records I find that in using it early in acute gonorrheal rheumatism, involving joints and ligamentous structures, I had failure in only one instance, and in considering this case in its last analysis I find that it was in reality of great value, though at the time I had thought it to be a failure. So that I have come to look upon this serum as a specific in the treatment

*Read before the American Urological Association, Atlantic City, June 7, 1909.

of acute gonorrheal rheumatism especially in those cases occurring early in a primary gonorrhea. The pain and swelling quickly subside, and many cases recovered inside of a week or ten days.

The case to which I referred was a man 38 years old, a Swede, who came to the dispensary in July, 1906, when we were using the rabbit serum obtained from Dr. Torrey. The man presented himself with a profuse purulent gonococcus-bearing discharge of ten days' standing, and shortly after treatment was commenced he began to have pain and swelling in both knees and feet and the right shoulder joint. For nearly a month he received the serum, 2 c.c. in either arm; he rapidly lost weight and strength, losing in that time fully fifty pounds. The discharge continued profuse in spite of treatment; the urine was very cloudy. And while he had a certain amount of comfort following the injection of serum, yet on the whole he seemed to become worse and was going downhill. It was with great difficulty that he could get to the dispensary, but that being the nearest place that he could get relief was probably the reason we did not lose him as a patient. The muscles were atrophied, especially those of the right arm, which he could not move except by lifting with the left hand, and when lifted the scapula moved outward showing anchylosis at the shoulder joint. It occurred to me to examine his urethra. I found a stricture admitting a No. 16 F. at 2½ to 3½ inches (the patient had had one previous attack of gonorrhea fifteen years before but no other in the interval). The stricture proved to be very amenable to treatment, for in ten days I was able to dilate the canal up to 30 F., when all his pain suddenly subsided, the discharge ceased, the urine cleared, his appetite returned, and he rapidly began to regain flesh and strength, and by the middle of September had regained his former weight. The right shoulder was the last to return to normal and did so gradually and he finally regained complete motion at the shoulder joint. He received a few more injections of the serum. The phases of this case are sufficiently striking without going into the question of the benefit derived from the serum, but I attributed his rapid recovery to the fact that he was well filled with the serum at the time I attended to his urethral lesion.

In the chronic cases of gonorrheal rheumatism we do not see the prompt action of the serum we do in the acute cases, and they are very prone to relapses generally due to some indiscretion, either from alcohol or sexual excitement when they are feeling comparatively well. In these cases thorough investigation of the urethral canal, the prostate and vesicles, and especially the posterior urethra must be made and carefully treated, and when this is done the serum has in my hands proven of great assistance in removing the pain and swelling, while it is only of temporary benefit if these measures are neglected.

Next I have found the serum of great assistance in epididymitis, both acute and relapsing; here again relapses occur if treatment is given up too soon. In many cases when given in the earliest stages I have seen the disease aborted. Of such value have I found the serum in these cases that although in the past two years I have looked for cases on which to perform the Hagner operation for epididymitis, I have not yet met with a case when I felt justified in using it, though I have made use of the Belfield method of opening and irrigating the vas with success in some cases of relapsing epididymitis.

In cases of acute prostatitis and vesiculitis the serum has proven of marked benefit in relieving the pain and shortening markedly the attack. A. M., 20, a college student, came to me last winter with a gonorrhea of two months' standing. He had just recovered from the severity of a posterior urthritis, in fact he was just out of bed. He was obliged to return at once to his college and could only come to New York twice a week traveling on the cars. At the end of the first week he complained of severe pain in the rectum. On examining the prostate I found it much swollen, hot, and tender. I gave him 2 c.c. of the serum in addition to the usual treatment, and he returned that same day for a mid-year examination the following day. I saw him again four days later and there was hardly a trace of the swelling; he said the pain had left him by the following morning.

As regards the bacterins, my experience is still very limited. I believe they are more easily prepared, and for that reason the cost may not be so great (of this I do not know). It would also seem to me more easy to obtain an autogenous culture, though with such I have had no experience.

I used bacterins prepared and furnished me by Parke, Davis & Co. I have used tubes at first containing 10 millions to the c.c., then 20 millions, and latterly 50, 100, and 500 millions to the c.c. These I have used at present only in dispensary work, as I have used the serum only in private work. At present I begin on a case with a vial of 1 or 2 c.c., containing 50 million bacteria; in forty-eight hours I give 100 million, and two days later 500 million. My impression so far has been that while I have seen good results, still the action seems to be slower than with the serum. I have not seen any marked ill results in using this large number of bacteria, have had no complaints of high fever, etc., nor have I seen any of those reputed results. Some cases which had previously had the serum have expressed themselves as noting better results with the serum and have asked for it in preference; others seemed pleased with the results. I have used the bacterins in gonorrheal rheumatism and epididymitis. One thing I have, I think, noticed, and that is that the local reaction, pain, and swelling of the arm followed by urticaria I have not as yet noted with the bacterins, while it is a very common incident with the serum.

THE USE OF ETHYL CHLORIDE AS A GENERAL ANESTHETIC FOR OPERATIONS IN THE THROAT AS ESPECIALLY APPLIED TO CHILDREN.

By E. MATHER SILL, M.D.,

NEW YORK.

ATTENDING PHYSICIAN IN DISEASES OF CHILDREN AT THE GOOD SAMARITAN DISPENSARY, LECTURER IN DISEASES OF CHILDREN AT THE NEW YORK POLYCLINIC HOSPITAL AND MEDICAL SCHOOL.

The choice of an anesthetic for the removal of tonsils and adenoids in infants and young children is a matter of no small importance since the success of the operation or even the life of the child may hinge on the administration of the proper anesthetic in a given case.

A child that has adenoids, adenoids and hypertrophied tonsils, or hypertrophied tonsils alone, not infrequently has hypertrophy of the lymphoid tissue elsewhere, such as enlarged cervical glands, en-

larged bronchial lymph nodes, enlarged thymus, etc., and, in fact, when operating upon cases we have not had under observation we are never quite sure that we may not be dealing with a case of "status lymphaticus." It is, therefore, of prime importance that an anesthetic be given that after extensive use has proved to be the safest. An anesthetic that fulfils this requirement, I believe we have, in ethyl chloride, but to say that there is no danger (even though it may be ever so slight) attached to any general anesthetic is a fallacy. I have used it as a general anesthetic with the Ware inhaler and the improved Ware inhaler in over 500 cases of operations for the removal of tonsils and adenoids, on infants and young children without a fatality or any serious results of any kind. Of this number there was only one case, that of a very anemic boy, in which it was thought necessary to administer hypodermic stimulation. There were two other children that did not take the anesthetic well. They became somewhat cyanosed and one of them stopped breathing for a short time and had to be resuscitated. It was found that this child had a severe bronchitis, which had been overlooked. It is my opinion that these three disagreeable experiences were largely due to the fact that these children, contrary to orders, had eaten

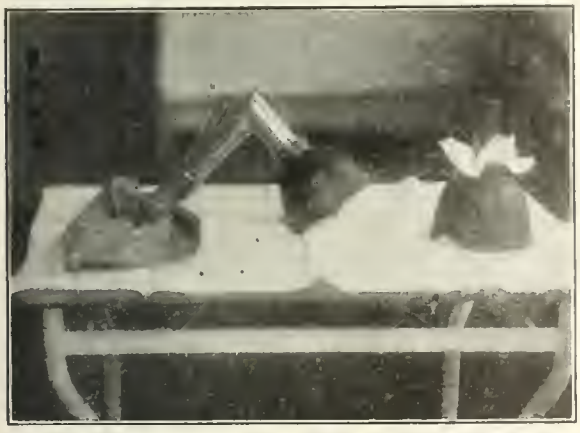

Fig. 1.—The Ware inhaler for ethyl chloride; the original is seen on the right, the improved form on the left.

within a short time of the operation, and to the fact that the vomitus, adenoid tissue, and blood were in a measure aspirated into the trachea; and also to the fact that the patients were not carefully examined before operation. Upon lowering the head and pulling the tongue and jaw forward the children cleared the trachea and were quickly revived.

The anesthetic was given by my assistants, who were, at this time, inexperienced in its use, and in these few cases too much was probably given and the child became too profoundly under its influence before attention was drawn to the fact. In such cases I remove the cone and allow the child to breathe pure air for a minute or so before beginning the operation. The child feels no pain in this operation when it is not so profoundly under the influence of the anesthetic and its reflexes are much more active, so that immediately upon completion of the operation and removal of the mouth gag, the child coughs and expectorates all blood and adenoid tissue.

Before beginning the use of ethyl chloride I had used chloroform in quite a number of cases when operations for the removal of tonsils and adenoids were necessary and had had several unpleasant experiences, which I should not like to have repeated. In these cases the child's breathing became slow and shallow, there was extreme pallor, the pulse became weak and irregular, and it was necessary to abandon the anesthetic entirely, give hypodermic stimulation, and then proceed with the operation. On inquiry among my colleagues I find that they have had similar experiences, and have given up the use of chloroform for adenoid and tonsil operations in children and are using laughing gas and ether anesthesia, or ether by the drop method. The consensus of opinion now is against the use of chloroform in the lymphatic diathesis.

My experience (and it has been pretty extensive since I have performed over 1,000 operations on children for enlarged tonsils and adenoids, and of these quite a number received chloroform—before the series of 500 cases where ethyl chloride was used, has borne out the fact that chloroform is a dangerous anesthetic in this lymphatic condition in which it is not infrequent to have hypertrophy of other lymphoid tissue and glands. Although I have never had a fatal result from its use, I have heard of fatal cases. On the other hand I have never seen any ill results occur from the use of ethyl chloride properly given, other than the cases above mentioned.

I have had no postoperative hemorrhages in any of my cases, but infection did occur in several cases causing sore throat, an elevation of temperature, and stiffneck for a while, in spite of the fact that great care was used in the way of asepsis and sterilization of instruments. This could almost be expected in such a large series of cases.

Ethyl chloride given by means of the Ware inhaler is the easiest of all anesthetics to give, and a novice can in a short time become almost an expert at giving it, although, of course, the same care and precaution should be taken as for other anesthetics. Only two or three thicknesses of gauze should be used over the inhaler, and the tube should be removed at intervals to see that the gauze does not become frosted over. In such case it should be changed, as it then prevents both air and ethyl chloride from entering the lungs and the child will become cyanosed. When the inhaler with the rubber bag is used this precaution is not necessary as no gauze is used, the ethyl chloride stream going directly through the small metal tube into the rubber bag. I prefer the rubber bag inhaler since with this the patient gets less air and is under the influence of the anesthetic quicker, and less ethyl chloride is lost in the giving and consequently less is required; but practically the same result can be obtained with the original simple inhaler by placing the thumb over the metal tube at intervals and in that way regulating the amount of air taken in and at the same time preventing the escape of the ethyl chloride. Dr. Ware has used this anesthetic in 8,000 surgical cases both in children and adults, some of which necessitated the patients being kept under for some length of time, with none but favorable results, and in all this number he never had a fatality. He believes it to be one of the safest and the most convenient general anesthetics.

When the anesthetic is properly given it usually takes from two to five minutes before the patient is sufficiently under its influence to proceed with the operation. I do not wait for the child to be profoundly anesthetized but operate when there is complete relaxation, but the eye or conjunctival reflex is still present to a slight degree. Unless there are

imbedded tonsils which require to be dissected out, this gives us plenty of time for the operation as ordinarily done. I have used it with satisfaction where slight dissection was necessary, or enucleation was done before the patient became conscious or felt any pain. Immediately upon the completion of the operation and removal of the mouth gag the little patient is conscious, coughs, cries, and expectorates all blood and adenoid tissue. There is no tedious waiting for the child to come out from the influence of the anesthetic as in chloroform and ether anesthesia. I always operate with the patient lying flat on the operating table with the head slightly lowered. This position is the safest on account of the heart and prevents aspiration into the treachea of blood and adenoid tissue in case the reflex cough does not come quickly enough to expel them. I have watched these cases carefully and find that after the first short struggle, which has occurred in a little over half of my cases, the child breathes regularly and quietly. There is usually some acceleration of the pulse, but I believe this to be due more to the fright and struggling of the child before becoming unconscious than to the anesthetic, although I believe ethyl chloride is a cardiac stimulant given in this way.

To sum up, we have a comparatively safe and reliable general anesthetic in ethyl chloride, which is most suited for operations for the removal of adenoids and tonsils in children. This anesthetic is simple of administration and does not require an expert or one of large experience to give it. The patient is under the influence quickly, is out almost immediately upon completion of the operation; there are no unpleasant or dangerous effects from its use either during or after the operation. This anesthetic is not only especially applicable in operations in the throat, but should be used in most of the other operations performed upon children. When the inhaler is kept over the patient's nose and mouth he can be kept under the anesthetic as long as desired. It is only when that is removed that the patient regains consciousness more quickly than with other anesthetics. Where long operations are necessary on the nose or throat I advise first putting the patient under ethyl chloride and then continuing deep anesthesia with ether using the drop method.

It seems to me ethyl chloride as a general anesthetic should find a large field of usefulness in dentistry.

INTERSTITIAL KERATITIS IN ACQUIRED SYPHILIS.

By S. LATIMER PHILLIPS, M.D.,

SAVANNAH, GA.

In the issue of July 31 of the Medical Record, Dr. Burton Chance of Philadelphia reports a most interesting case of parenchymatous keratitis in acquired syphilis. This suggested to me a case which came under my observation during the latter part of 1890, and was of so much interest to me with its probable sequences that I report it below with some further notes on this case and that of her son.

Mrs. ——, thirty years old, and a widow of five years standing and mother of two healthy boys, one nine, the other seven years old, consulted me, December 18, 1890, in reference to her failing sight, which she had noticed for the past three months. Not strong and in reduced circumstances she was using her eyes constantly by day and night to make a living for herself and her children. At first what was a slight blur gradually grew worse, until the time when she sought aid, when she seemed to see all objects through a thick veil—vision, right, 20/70; left, 20/50. Sewing was now impossible. She had never had pain in the eyes, or head, or photophobia, nor was there any congestion of the conjunctiva. Through it all the eyes never showed the slightest redness. There was no iritis, and under atropine the pupils dilated freely and clear of all adhesions. In each corner there was a gray central opacity, with edges clearly defined, leaving a rim of perfectly clear corneal tissue between the clouding and the corneoscleral junction. In each eye the clouding took somewhat of the form of a crescent, with the concavity below, thus leaving more clearness in the lower half of the cornea than the upper. With the ophthalmoscope, details of the fundi could not be made out. Clouding involved the superficial and middle layers of the cornea only. After inquiry, patient acknowledged that over a year, or nearly two years, previous she had lost much hair from her head and had suffered much from sore throat.

Making a diagnosis of syphilis she was put on increasing doses of bichloride of mercury and potassium iodide, varied with inunctions of mercurial ointment. For a week or ten days clouding increased in intensity and vision became materially worse. After that, however, it began steadily to improve without a setback until the following May, five months after the inauguration of the treatment, when she was discharged with v. = right, 20/30; left, 20/20. Cornea perfectly clear. Eyes still slightly under the effects of atropine. General health good. I did not see her any more professionally until six years later, when she appeared with a baby boy two years old suffering from enlarged tonsils. She had married in the meantime a man who, previous to her marriage, had been under my care for a chronic throat trouble of a catarrhal nature, with history of tuberculosis in his family. A few years later the son developed trouble in the knee joint and was under the care of the late Dr. Phelps of New York until he died. The mother developed some lung trouble and died in Asheville, N. C., about 1902 or 1903, of tuberculosis, so said. The son, under Dr. Phelps treatment got well, with a slight limp. The father, wishing to better his condition, if possible, took him to a physician who advised breaking and resetting the limb. This was done, with no improvement of the condition. In 1905 the father asked me to see the boy in consultation. He was in a hospital where the attendant physician had sent him. He was tossing about, holding his head in his hands and complaining of intense headache, and crying out in agony. Temperature, 103°. An ophthalmoscopic examination revealed optic neuritis. Diagnosis, tuberculous meningitis. Notwithstanding all that could be done the boy died a few weeks later, aged eleven. It has been very interesting to me to follow the above case through another generation and see how nature has worked according to her own laws.

Alexander (Syphilis und Auge, Wiesbaden, 1889) mentions having seen in his practice thirteen cases of keratitis parenchymosa, where there was no trace of heriditary syphilis, the first symptoms of corneal trouble appearing from two to three years after outbreak of acquired syphilis. He mentions Leber as having seen it in connection with

syphilitic retinitis. Jakolewna twice in sixty-three cases of acquired syphilis; once simultaneously with eczema, ulcerated pharynx, and condylomata, the other with ptosis. Mauthner, a severe case in a suckling, who had contracted syphilis from the wet nurse. Ancke in thirty-seven cases dependent upon syphilis, ten times in acquired syphilits. Schadeck saw a case of laryngitis, periostitis, and frequently recurring iritis, in which double parenchymatous keratitis broke out, and was controlled only by a long course of mercury and potassium iodide.

232 Bull Street.

A NEW PHYSICAL SIGN, PROBABLY A SKIN REFLEX, WHEREBY SOLID ORGANS, SUCH AS THE HEART AND LIVER, AND INFLAMMATORY PROCESSES FOUND IN THE LUNGS AND PLEURA MAY BE DETECTED BY PALPATION.*

By F. M. POTTENGER, A.M., M.D., LL.D.,

MONROVIA, CALIFORNIA.

While working out the sign of muscular rigidity in diseases of the pulmonary parenchyma, as described in the *American Journal of the Medical Sciences,* May, 1909, I found still another sign which greatly enhances the value of palpation as a procedure in physical diagnosis, and which aids in the outlining of normal organs as well as in the determining of pathological conditions. This sign consists of a feeling of resistance to the palpating finger when pressed gently upon the skin. To determine the presence of this sign it is well to begin at some little distance from the edge of the organ, or if it be an inflammation or infiltration that is to be outlined, it is well to begin over presumably normal tissue, and then by advancing toward the area whose limits are to be determined there will be noted a feeling of resistance when this is reached. While I am not sure just what produces this sign, yet it seems to me that it is most probably a skin reflex, produced by the contraction of the erectores pilorum. But even if this be the explanation of the phenomenon, it is still necessary to explain what it is that makes these muscles contract under normal conditions in such a manner as to delimit healthy organs, and also in the presence of disease so as to outline inflammatory processes.

While it is somewhat difficult to give a clear idea of this sign by description, it is easily demonstrated on the living subject. The heart can be easily and accurately outlined by it, the liver dullness, both relative and absolute, can be determined, and the areas of infiltration in the lung can be mapped out with surprising accuracy.

One thing that is difficult to understand is that this sign shifts with the organ. We might conceive of a certain connection between the skin immediately overlying an organ and the organ itself, but to explain shifting of the sign to other areas of the skin when the position of the organ changes is difficult. When the heart shifts, as it does in diseases of the lungs and pleura, the sign shifts with it. I have found it to follow the heart when the organ was entirely to the left of the sternum, and also in a case of dextrocardia, in which the entire organ was to the right of the sternum. I have also found it to follow the edge of the liver when it was three finger breadths below the costal border.

Its accuracy is proven by percussion and auscultatory percussion, in the case of the heart and liver, and when checked by both percussion and auscultation in a case of infiltration of the pulmonary parenchyma.

Note.—Since writing the above, I have had an opportunity to study this sign more fully, and am now convinced that it is not a muscle reflex, because it can be found on the cadaver the same as on the living. It probably depends on the difference between tissues of different density.

I have proven the sign, in case of the heart, with the orthodiagraph, and am surprised at its accuracy.

*Read before the American Climatological Association, Old Point Comfort, Va., June 4 and 5, 1909.

New Observations on the Mechanism of the Production of Transitory Albuminuria in Children by Experimental Lordosis.—A. Mori has never obtained transitory albuminuria by lordosis in the horizontal position. He has studied in the obstetric clinic of Milan a collection of fetuses fixed in a position of lordosis at various vertebral levels, and has experimented on rabbits and guinea pigs, and believes that we can exclude any rotation of the kidneys on their vertical axes from the production of albuminuria by stasis of blood in the renal veins. The vertical position is necessary to the production of albuminuria. The stimulus of the splenic plexus must be reckoned with in the production of albuminuria by lordosis, as well as the vasomotor disturbances in the vena cava ascendens and its branches at the level of the lordosis produced, and the compression exercised by the kidney and liver disturbances.—*La Riforma Medica.*

Postrubeolic Diphtheritic Conjunctivitis.—E. Weill and G. Mouriquand describe a small epidemic of diphtheritic conjunctivitis following measles, witnessed by him, in which the cases were all fatal. There are two kinds of diphtheritic conjunctivitis—a less severe one, in which there is a false membrane involving the lids alone, and a severe form, in which there is no false membrane, but the ocular and palpebral conjunctiva are both involved, and the interstitial inflammation generally causes ulceration and perforation of the cornea and loss of the contents of the eye. The Klebs-Loeffler bacillus is found in the exudation. The severity of the measles bears no relation to the occurrence of the complication. There is rarely a pure culture of the diphtheria bacillus but staphylococci or streptococci are present with it. Treatment is of no avail, and the children died in all the cases seen by the authors.—*Archives de Médecine des Enfants.*

Ovarian Opotherapy.—Paul Dalché makes use of ovarian opotherapy, or the treatment of irregularity and deficiency of the ovarian function in a number of conditions. The indications include ovarian dystrophies, shown by flashes of heat and cold, headache, insomnia, and such troubles; hyperactivity of the ovaries; ovarian ataxia, with irregularity of menstruation; cephalalgia of puberty; polyglandular syndromes, consisting of variations in the functions of the suprarenals and thyroid; genital accidents, including amenorrhea, dysmenorrhea, and metrorrhagia; some cases of chlorosis and anemia; goiter and Basedow's disease; localized obesity; psychoses; chronic rheumatism after the menopause, and surgical menopause. It should be in the form of ovarian powder, powdered corpus luteum, peptonized ovarian substance, or glycerinated extract of ovaries. The treatment must be continued for a long time in order to get the best effects.—*La Gynécologie.*

The Ovular Theory of the Pathogenesis of Eclampsia.—E. Opocher, after careful examination of all the clinical and experimental material with reference to the cause of eclampsia of pregnancy, concludes that there is not sufficient proof of the theory that the poisons producing the convulsions are generated by the metabolism of the fetus. To consider the eclamptic poisons as the products of the fetus is contrary to the dictates of physiological obstetrics and of observation. The placenta would not be capable of the neutralization of these products in cases of pregnancy going on to its end without eclamptic manifestations. Although the placentar theory is attractive from a theoretical standpoint, it is not proven practically by experiment or observation. The theory that is best substantiated practically, and that best accords with modern knowledge, is that of the production by the maternal system of antitoxines which prevent the appearance of eclamptic symptoms as a result of systemic poisoning.—*Folia Gynæcologica.*

MEDICAL RECORD.

New York, October 23, 1909.

THE ETIOLOGY OF LEUKEMIA.

A FEW years ago a prominent English physician, in discussing a case of leukemia, compared the usual method of investigation of such diseases by frequent differential counting of the blood cells, to trying to find the reason for a street gathering by counting the styles of hats worn by the crowd. As a preponderance of silk hats might suggest a wedding and an excess of cloth caps a meeting of the unemployed, so an abnormal number of lymphocytes, eosinophiles, or myelocytes may give slight suggestion of the reason for their presence. The peculiar blood picture, however, is itself neither the disease nor its cause, but is the result of some more deeply seated stimulus; and in order to determine the etiology of the especial condition in question attention must be paid less to the peculiarities of the cells produced and more to the primary cause. To return to the simile, to prove the cause of the crowd, we must overlook the hats and search for the bride and the demagogue.

That this is becoming more widely recognized is shown by a review of the recent literature on acute leukamia. Each year less attention is paid to the hematological differences in the cells themselves and more to the search for parasites in the blood. In recent years four articles have appeared reporting new structures found in leukemia, each suggested as a possible cause of the disease. In 1900, Löwit presented his monograph on the *Hæmameba leukæmiæ;* in 1905 Auer discovered various peculiar intracellular structures; in 1907, Löwit again came forward with a different parasite, a flagellated organism found in the blood and lymph glands at a post-mortem examination; and finally White and Proescher, in 1908, reported spirochetes in the lymph glands, not only in acute leukemia, but in pseudoleukemia and lymphosarcoma as well. As these findings were, however, all isolated observations, and with one exception have not been confirmed by later investigation, but little weight has been given to the discoveries. The exception is in the case of the structures observed by Auer in 1903, and described by him in 1905. These findings have been confirmed twice, and for that reason the so-called "Auer's bodies" are deserving of especial attention. They were seen by their describer in the blood of a patient who died of acute leukemia in the wards of the Johns Hopkins Hospital. As described by Auer, they were of three kinds, pulsating vacuoles, refractile granules, and rods. They appeared only in the large lymphocytes and were seen in the fresh blood as well as in that stained by several of the usual methods. The pulsating structures were intranuclear and in the fresh blood actively changed both their size and shape. In the stained smears they were seen as indefinite pale blue areas in the more deeply colored nuclei. The granules and the rods were found in the cytoplasm only, and in the fresh specimens appeared to be highly refractile. The granules were so numerous that many of the cells resembled myelocytes, and they stained a dark red or bluish red with Leishman's stain and a pale brown red with Ehrlich's. The rods were the most characteristic of the structures observed by Auer. They occurred in from six to ten per cent. of the large mononuclear cells, were one to six micra long, as a rule lay near to and parallel with the edge of the nuclei, and stained similarly to the granules. Unfortunately the inability to obtain permission for an autopsy on the patient prevented the author from carrying his experiments further.

Shortly after the appearance of Auer's paper Pappenheim stated that in one case of leukemia he had seen similar structures; in July, 1909, Barker also saw them in one case, and in the *American Journal of the Medical Sciences* for October, 1909, Ottenberg reports three cases in which the rods were found, two of acute lymphatic leukemia and one of chloroma. The rods were in much smaller numbers than in the original case of Auer. The granules Ottenberg states to be indistinguishable from the azurophile granules found in normal blood, and as apparently no study was made of the fresh blood, the pulsating intranuclear structures of Auer are not mentioned. Efforts to grow the Auer bodies in various culture media failed, and smears from the spleen, bone marrow, and lymph glands did not show the rods—possibly due to the degeneration of the cells. Efforts to reproduce the disease in monkeys by inoculation were unavailing.

This practically covers the present status of knowledge as to the parasitology of leukemia. The findings of Löwit and of White and Proescher have as yet not been confirmed. The structures described by Auer have been seen by four observers in six cases. They have been seen, but nothing more. They have not been grown and have not produced the disease in animals. They have, however, been observed in six cases of leukemia and in no other diseases nor in health. As they have been seen in fresh blood as well as in stained specimens the possibility of their being artefacts is ruled out. The rods suggest parasites, but there is no absolute proof of their being such while the vacuoles are claimed by some to be found in normal cells. In short, we are far from having proof of the etiology of leukemia. The finding and confirming of these Auer's bodies, however, would seem to offer more encouragement than any other recent discovery in connection with leukemia, and it is possible that further research in this direction may be fruitful

in adding to our knowledge of this mysterious and fatal disease, if a symptom complex, possibly the result of various pathological processes, may justly be designated as a disease. Further observations may at least be expected to demonstrate the true nature of the structures described by Auer, when it is probable that they will be given a name more scientific and descriptive than that with which we at present cloak our ignorance—the name of their discoverer.

Possibly worthy of mention *en passant* are the three instances cited recently by Nicolle and Cassuto in which, in cases which they consider to be van Jaksch anemia infantum pseudoleukemia, typical Leischman-Donovan bodies were found, which were grown on culture medium and at a later period successfully innoculated by Novy into dogs. The question of the entity of van Jaksch's anemia is however so widely criticised, and the blood findings in Nicolle's case are so atypical of the disease as it is at present understood, and so suggestive of a simple inflammatory leucocytosis as it appears in the infant that it hardly seems justifiable as yet to base any theories upon these findings.

THE MODE OF INFECTION AND THE INFECTIOUS PERIOD IN SCARLET FEVER.

In a lecture before the Harvey Society Dr. David L. Edsall once said that nothing succeeds better than a few figures in determining whether our conceptions are scientific or "fine art." This remark is very applicable in connection with a study of scarlet fever published as the Fiske Prize Essay by the Rhode Island Medical Society. The author, Dr. Charles V. Chapin, was Health Officer of Providence, Rhode Island, and had, therefore, access to first-hand evidence in the matter of the spread of infectious diseases. He has prepared for his essay a number of tables which in part bear out the common beliefs in the subject and in part contradict them or disprove them altogether. The usual teaching in regard to the shortness of the period of incubation is well borne out by his figures, two or three days being the rule, though exceptionally it may extend to any number of days within three weeks. That the disease is very infectious in its early stages is likewise shown by the number of secondary cases developing in families after a child has been removed to an isolation hospital. Contrary to the usual belief, however, the data indicate that the infectivity rapidly declines with the diminution of the throat symptoms and the disappearance of the rash. On the other hand, a small number of patients remain infective for a long period, a fact well proved by the occurrence of the so-called "return" cases of the English, cases, that is, traceable to children sent home from isolation hospitals. It is in this connection that Chapin brings out the little known fact that the infectivity is probably kept up by the chronic discharge from the nose or the ear, which is a frequent sequence of scarlet fever or one of its complications.

The old belief in the infectivity of the desquamated epidermis is quite shaken by the statistics obtained by Chapin and those quoted by him from the English observers. Priestly, of Leicester, discharged 120 scarlet fever patients in the period of desquamation and yet no secondary cases developed in any of the homes. Lauder, at Southampton, succeeded in reducing the percentage of "return cases" from 4.27 to 2.15 in the course of one year by paying special attention to the mucous membranes while neglecting desquamation. At the same time the length of stay in the isolation hospitals was shortened by these measures from forty-eight to thirty-four days. These data show the falseness of the oft-quoted analogy between smallpox and scarlet fever. Indeed, it is rather diphtheria that scarlet fever resembles most closely, for the pathological process caused by the unknown excitant of the disease is for the most part confined to the mucous membranes, the rash being probably due to the toxins elaborated in the throat. This argument speaks *a priori* against any great infectivity of the desquamated skin, while the absence of direct proof of such infectivity is well shown by the experience of the English observers quoted above. The numerous cases in which no lesions have been found and which have, nevertheless, proved infective may quite reasonably be classed with so-called "carriers" of the disease, such as are met with in typhoid fever, etc.; such an explanation is much more probable than tracing the infection to a small portion of desquamating epidermis not discovered at the time of discharge. Of course, the final proof of such assumption must await the discovery of the specific excitant of the disease.

Most interesting is Chapin's discussion of the modes of infection in scarlet fever. His statistics show that this disease almost never travels from one family to another in the crowded tenement houses of cities, which fact throws great doubt on the frequency of infection by fomites. Certainly the mothers, brothers, and sisters of the patient infect numerous articles in the tenement houses, such as the woodwork in the halls, the rails of the stairways, the knobs of the street doors, etc., and yet these inanimate objects do not spread the infection. That fomites occasionally spread the disease is not to be doubted, but that they play any important rôle in this connection the author regards as quite improbable. The bugbear of airborne infection, too, falls with the proof that the desquamated skin is very little if at all dangerous, yet this belief is established so firmly among lay circles that the foundation of an isolation hospital is frequently met with insuperable objections from members of legislative bodies representing the population of the neighborhood. The best practical evidence we have that scarlet fever is not airborne is furnished by the Pasteur Hospital in Paris, in which patients with different diseases are cared for in separate rooms opening out of a common corridor. Of two thousand such patients admitted one winter ninety-two had scarlet fever, but in no instance did any one in the hospital contract the disease. In the great majority of cases scarlet fever is spread by direct contact with the patient. There are a thousand and one ways in which children can transfer infective material whether by immediate contact or through the

medium of an object, such as a glass used in common or a pencil held in the mouth by the sick child. Toys, cups, spoons, candy, etc., etc., may thus become the carriers of secretion from one child to another and spread the disease. The *rôle* of contact is shown still further by the greater prevalence of scarlet fever among women over sixteen years of age than among men, for women, of course, come into much more intimate contact with the sick children than the men of the family.

Dr. Chapin's study puts great stress upon the importance of the recognition and isolation of early cases of scarlet fever, for these are the cases that spread infection broadcast. The importance of the pathological conditions of the mucous membranes in keeping up infectivity must also be kept in mind by health officers as well as by private practitioners. It may be that the results obtained by Lauder can be duplicated in this country, greatly to the advantage of the patients as well as of the community, if desquamation is less thought of than the cessation of aural or nasal discharge, in determining the duration of isolation after an attack of scarlet fever.

FUNCTIONAL NEUROSES OF CHILDREN.

This term covers a very wide range of children's complaints, far too wide a range indeed to be discussed even in the most cursory manner in a single column. There are, however, a few of the most prominent of these neuroses of children which may be briefly touched upon. As J. A. Coutts of London pointed out at the recent meeting of the British Medical Association, several of these neuroses begin in earliest infancy. For instance, cases of faulty deglutition, where an infant rolled and gargled each mouthful of milk at the back of the pharynx for some time before finally swallowing it. Sometimes such cases improve with the thickening of the food at the appropriate age, but in other instances the difficulty commences with the thickening of the food. Defective respiration is a much rarer neurosis of infancy and at the same time far more dangerous. Both faulty deglutition and defective respiration are to be ascribed to defective training of the nerve centers concerned with deglutition and respiration respectively. As to the pathology of pyloric stenosis Coutts himself considered it unsettled, but as most authorities consider that it arises solely from spasm he felt justified in including it among the functional neuroses. Some authorities advise operation, while Hutchinson and others hold the view that in no circumstances should operation be performed.

In regard to the neuroses of later childhood Coutts was of the opinion that cyclic vomiting was merely a phase of migraine. Family histories and sequelæ confirmed the identity of the two complaints, although typical migraine as witnessed in adults was rare in children before the age of puberty. The form it took in young children was that of recurrent attacks of pyrexia and drowsiness, together with a certain amount of headache and vomiting, and was usually looked upon as simply an attack of biliousness. Migraine in infancy was extremely uncommon, but in these cases the attacks in later years were generally of a severe and intractable type. Incontinence of urine, was, according to the author of the paper, frequently treated in an unsatisfactory way. Leonard Williams has recently given reasons for attributing the disorder to thyroid insufficiency, and has claimed great success for its treatment with thyroid extract. Nervous diarrhea was as frequent perhaps among adults as among children. In the treatment of this affection nerve sedatives, such as the bromides, with temporary limitation of the carbohydrates in the diet, had proved more efficacious in the hands of the author than the treatment by arsenic, as recommended in the text books.

The simple tic or habit spasm up to a comparatively recent period has been regarded as a phase of chorea, but it is now well established that the complaint frequently arises from some local exciting cause, and the first step in treatment should be a reliable examination of such parts as the eyes, ears, throat, and teeth. Further than this chorea is, according to the experience of the author, never strictly unilateral.

In the discussion that followed the reading of Coutts' paper, many of the foremost British authorities on children's diseases took part and several interesting points were raised. G. E. Shuttleworth drew attention to the fact that emotional excitability in children was very commonly associated with moral perversion and disregard of truth, neuroses passing into psychoses. Mental obsessions, he thought, sometimes developed from impressions received through children's picture books, which led often to morbid fantasies. Regarding hypertrophic stenosis of the pylorus, Harold Stiles said it could be remedied only by operation, but such cases were rare, whereas instances of pyloric spasm were common, often resulting from change of diet or being associated with chronic trouble in the appendix.

That neuroses of every description are on the increase in all civilized countries is well known to medical men. It is a sign of the times and a necessary corollary to the manner in which we live. Infants born and brought up in towns, and whose parents are frequently of unbalanced or unstable nervous temperament, can hardly fail to suffer from neuroses. It is a penalty of so-called advanced civilization. In endeavoring to cope with such affections, the first and main object is to strike at the root of the evil and to attempt to better the conditions under which the majority of the dwellers in towns live. Treatment is essential, but prevention must be the chief aim.

Heart Failure Cells in the Urine.

Epithelial cells containing brown pigment granules occurring in the sputum have long been considered of diagnostic value, their appearance associated with the chronic passive congestion of heart disease having led to their being commonly known as "heart failure cells." Similar pigment granules have also been noted in the kidneys during congestion, the various pathologists who have studied them having stated that the pigment is of two types, large dark brown or black masses found in the neighborhood of hemorrhages, and light yellow to brown-

ish yellow granules occurring in the epithelium of the tubules without association with gross hemorrhage. These cells have been shown to be similar to those found in the lungs in that they are of epithelial origin but to differ from the latter in that the granules are rarely composed of hemosiderin. While the presense of such granules in the kidneys has been up to the present of little more than academic interest, an article by Bittorf in the *Münchener medizinische Wochenschrift* for August 31, 1909, holds out the hope that they may prove to be of actual, clinical, diagnostic importance. This hope is based upon the author having found such cells fairly constantly in the urine in cases of passive congestion of the kidneys as a result of heart disease. The cells found in the urine are of the type containing light yellow granules. They are seen as more or less swollen, polymorphous, but usually polygonal, cells of various, often large, sizes, with indistinct, large, round nuclei. There may be several together or they may be attached to casts. Their occurrence in the urine, associated with casts and a few scattered red blood cells, is an objective evidence of a circulatory affection of the kidneys, especially if the common sources of kidney hemorrhage as tumors, infarcts, and acute nephritis are absent. It not infrequently happens that it is a difficult problem to differentiate between cases of primary myocarditis with secondary renal congestion and those of chronic nephritis with resultant cardiac lesions. In such cases the presence of these "heart failure cells" in the urine may be of some value in pointing to the heart as the source of the disease and the kidney as affected only secondarily. As to prognosis, Bittorf has found that in primary cardiac cases improvement in the general condition and relief of the congestion cause the disappearance of these characteristic cells from the urine.

Tuberculosis in New York.

A pamphlet has recently been distributed by the Committee on the Prevention of Tuberculosis of the Charity Organization Society in behalf of the increased appropriations needed to continue the anti-tuberculosis work in the city. In it are given some statistics as to the prevalence of tuberculosis in New York. In 1908, 10,147 died of the disease, the tuberculosis death rate not having decreased materially during the past seven years. There are at present in New York 44,000 known cases of tuberculosis, of which only 16,000 are under the care of physicians, leaving 28,000 unsupervised and uncared for in the tenement houses. Each year there are in the neighborhood of 24,000 new cases in the city. There are now on record over 8,000 patients of the unsupervised class, and 20,000 have been lost sight of. The granting of the increased appropriation will accomplish the following: (1) close and effective control of the consumptive poor in their homes; (2) monthly or biweekly visits to the tenement house patients; (3) diligent search for the 20,000 "not found" cases; (4) supervision of patients discharged from hospitals; (5) disinfection of infected apartments; (6) more thorough sputum examinations; (7) more adequate clinic treatment; (8) increased usefulness of the Otisville Sanatorium and the Riverside and Metropolitan Hospitals; and (9) proper care and education of children, both those with outspoken tuberculosis and suspicious cases. Every one who knows what has been done by the Health Department of this city, the tuberculosis work of which is looked upon as a model by sanitarians the world over, will hope that the appropriations asked of the Board of Estimate and Apportionment by the several departments will be granted. Without the additional means desired there is danger that most of the work already accomplished will be undone. Civic pride, if not pity and the instinct of self-preservation, should inspire the board to grant the comparatively slight increase demanded.

News of the Week.

Morton Commemoration Exercises.—Commemoration exercises were held at the Massachusetts General Hospital, on October 16, in honor of the anniversary of the first use of ether by Dr. William T. C. Morton. President Emeritus Charles W. Eliot of Harvard University delivered the address and spoke on the subject of animal experimentation, stoutly opposing the antivivisectionists and their ideas. There was exhibited a bronze bust of Morton, a photograph of which is here reproduced by the courtesy of Jno. Williams, Inc., of New York, the casters. It is the work of Miss Helen Farnsworth Mears of this city. The bust will have a permanent place in the Smithsonian Institute in Washington. The inscription on the base is as follows:

William T. C. Morton, M.D.
MDCCCXIX MDCCCLXVIII
Discoverer of surgical anesthesia. By whom pain in surgery was averted and annulled. Before whom in all time surgery was agony. Since whom Science has control of pain.

On the rear of the base is inscribed:

Modified and elaborated from an initial study for a bust made from life by Clark Mills of Washington, D. C., about MDCCCLXIV, which is in the Massachusetts General Hospital at Boston, Mass. Presented by William James Morton, M.D., a son of W. T. C. Morton, MDCCCCIX.

Army Medical Corps Examinations.—The Surgeon-General of the Army announces that the War Department has appointed permanent boards for the preliminary examination of applicants for appointment in the Medical Corps of the Army, to meet at Washington, D. C., Fort Sheridan (near Chicago), Ill., and San Francisco, Cal., in addition to the usual preliminary examination boards that are assembled at various army posts throughout the United States from time to time. The permanent boards will hold sessions on the second Monday of each month. A limited number of successful candidates will be appointed First Lieutenants in the Medical Reserve Corps (salary $2,000 per annum) and assigned to army posts until the next session of the Army Medical School, when they will be ordered to attend the school as "student candidates." Applicants must be citizens of the United States, between twenty-two and thirty years of age, graduates of reputable medical schools, of good moral character and habits, and shall have had a year's hospital training after graduation, or its equivalent. Full information concerning the examination can be procured upon application to the Surgeon-General, U. S. Army, Washington, D. C.

Superintendent of the Custodial Asylum for the Feeble Minded.—Under the civil service rules a competitive examination for the position of Superintendent of the New York State Custodial Asylum for Feeble Minded Women at Newark, N. Y., at $2,500 per annum and maintenance, will be held on October 30, 1909. Candidates must be men of medical training and experience who are interested in the care and development of the feeble minded and who possess executive ability sufficient for the management of the affairs of the institution. Application blank can be obtained on request from State Civil Service Commission, Albany, N. Y.

Harvey Society Lectures.—The first lecture of the series will be delivered on Saturday, October 30, 1909, at 8.30 P.M. in the New York Academy of Medicine, by Prof. Richard M. Pearce of the University and Bellevue Hospital Medical College, on "The Problems of Experimental Nephritis."

Dr. Bulkley's Lectures on Skin Diseases.—The governors of the New York Skin and Cancer Hospital announce that Dr. L. Duncan Bulkley will give an eleventh series of clinical lectures on diseases of the skin in the out-patient hall of the hospital, on Wednesday afternoons, commencing November 3, 1909, at 4.15 o'clock. The course will be free to the medical profession.

Medical Directories.—The Medical Directory of New York, New Jersey, and Connecticut for 1909, published by the Medical Society of the State of New York has just been issued. It contains the names of 16,785 registered physicians, 13,023 in New York State, 2,458 in New Jersey, and 1,304 in Connecticut. Of the 13,023 physicians in New York State, 4,865 reside in Manhattan and the Bronx, 1,778 in Brooklyn, 184 in Queens, and 62 in Richmond, a total of 6,889 for Greater New York. The appearance, promptly on time, of this complete and accurate directory reminds us of the directory long ago promised by the American Medical Association. Subscriptions were asked, and some received, for this book early last winter and the subscribers were then promised that the book would be issued in April or May. It is now October and subscribers are wondering whether, as in the case of trust companies in general, interest is allowed on deposits.

Fined for Selling Medicine.—A woman of Rock Island, Idaho, was found guilty recently of practising medicine and peddling drugs and ointments without a license on complaint made by the State Board of Health through its attorney. She was fined $100 and costs and appealed the case.

Dr. G. A. Gibson of Edinburgh, at the recent ceremonies accompanying the inauguration of President Lowell, received the degree of Doctor of Science from Harvard University.

Pellagra in Texas.—Twenty-one cases of pellagra are reported in Texas in the latest bulletin of the Texas State Board of Health. Ten cases were reported from central Texas, two from Dublin, three from Cleburne, one from Temple, one from Marlin, one from Powell, one from Warren, one from Ennis, and one from Austin.

State Hygienic Laboratory at Ithaca.—In connection with the central department at Albany, a branch of the State Hygienic Laboratory has been established at Cornell University to serve the needs of the surrounding counties. It is located in Lincoln Hall, the civil engineering building. Dean Haskell and Prof. H. N. Ogden, hydraulic expert for the State Health Department, will have supervision over it.

A New State Insane Hospital is to be established on Lake Mohansic, seven miles from Peekskill and a mile from Yorktown Heights in Westchester county. The site is across the lake from the site of the New York State Training School for Boys, and contains 550 acres. The new hospital will take care of the overflow from the State insane institutions in New York City. Buildings are to be erected on the site to accommodate 2,000 patients.

Pension Fund for Nurses.—Under the auspices of the Mount Sinai Training School for Nurses, a pension fund has been established for the benefit of nurses who have been graduated for more than ten years. This is the only pension fund of its kind in the United States. Until $60,000 have been contributed to the fund no claim can be considered, and up to the present time $25,000 has been donated.

Hospital Contests Will.—The Presbyterian Hospital in New York has opened proceedings to contest the will of the late Edward O. Kindberg. By a previous will the hospital was made residuary legatee by Mr. Kindberg. Shorly before his death, however, he made a new will by which the hospital received nothing. The allegations are that Mr. Kindberg was of unsound mind and that the will was obtained by undue influence and fraud.

Montefiore Home Reception.—Invitations have been issued for the celebration of the twenty-fifth anniversary of the Montefiore Home for Chronic Invalids and Consumptives, in New York, to be held at the Hotel Astor on the evening of Oct. 26. Among the invited guests who will be present and deliver addresses on that evening are Messrs. Seth Low, Robert W. de Forest, and Judge Samuel Greenbaum.

The American Society for the Study of Alcohol and Other Narcotics has erected a monument to the memory of the late Dr. J. Edward Turner, of Wilton, Conn. The dedicatory services at the unveiling of the monument will be held Oct. 27, 1909, at 2 P. M., at Wilton, Conn. Dr. L. D. Mason,

of Brooklyn, N. Y., president of this society, will give the dedicatory address. Other addresses will be made by Dr. H. O. Marcy of Boston, and Dr. T. D. Crothers of Hartford.

The East Side Physicians' Association.—A regular meting of this society will be held Thursday, October 28, 1909, at Scheffel Hall, 194 Third Avenue, at 8.30 P. M. The discussion of the evening will be on typhoid fever, the papers on this subject being by Drs. Darlington, Coleman, Isaacs, and Heiman.

The Delaware State Medical Society, at its 121st annual meeting, held October 12, at Dover, elected the following officers: *President*, Dr. Pressley S. Downs of Dover; *Vice-Presidents*, Dr. L. Heisler Ball of Faulkland and Dr. James Martin of Lewis; *Secretary*, Dr. George W. K. Forrest of Wilmington; *Treasurer*, Dr. S. C. Rumford of Wilmington; *Delegate to the American Medical Association*, Dr. J. H. Wilson of Dover; *Delegate to National Council of Medical Education*, Dr. H. W. Briggs of Wilmington.

The Bennington County (Vt.) Medical Society at the quarterly meeting held at Bennington, October 6, 1909, elected the following officers for the ensuing year: *President*, A. E. Houle of Bennington; *Vice-President*, Dr. G. V. Wager of North Bennington; *Secretary*, L. E. Hemenway of Manchester; *Treasurer*, Dr. F. W. Goodall of Bennington.

Pathological Society of Philadelphia, Pa.—At the annual business meeting held October 14 the following officers were elected for the ensuing year: *President*, Dr. David Riesman; *Vice-Presidents*, Dr. A. O. J. Kelly, Dr. D. L. Edsall, Dr. Allen J. Smith, and Dr. Jos. Sailer; *Secretary*, Dr. E. H. Goodman; *Recorder*, Dr. F. H. Klaer; *Curator*, Dr. H. T. Karsner.

Appointments.—Dr. William Egbert Robertson has been elected Professor of the Theory and Practice of Medicine and of Clinical Medicine in the Medical Department of Temple University, Philadelphia. Dr. Charles E. Nammack has been appointed visiting physician to St. Vincent's Hospital, New York City.

Obituary Notes.—Dr. JOHN PHILLIPS REYNOLDS of Boston died at his home, September 30, 1909, at the age of 84 years. Dr. Reynolds graduated from Harvard College in 1845, and from Harvard Medical School in 1848. He was instructor of obstetrics and medical jurisprudence from 1869 to 1877, and professor of obstetrics from 1877 to 1885 in the Harvard Medical School, resigning in the last named year. Descended from illustrious ancestors, Dr. Reynolds was himself for many years a prominent figure in the history of Boston, and for many years was a member of the Boston School Committee. He was a member of Suffolk County and the Massachusetts Medical Society.

DR. HENRY A. DEVENDORF of Hunter, N. Y., died at his home October 14, 1909, aged 83 years. Dr. Devendorf was a graduate of the Albany Medical College, but had retired from active practice many years ago.

Dr. MARTIN HALBERT CALKINS of Wyoming, Ia., died at his home, September 27, 1909, aged 81 years. Dr. Calkins was a pioneer physician in Iowa, having settled there in 1856. Besides his practice, he took a great interest in politics, having been elected the first mayor of Wyoming, and for two terms having served in the Iowa Legislature.

Dr. W. GREGG AUSTIN of Utica, Miss., died in his office, September 25, 1909, aged 41 years. He was a graduate of the Memphis Hospital Medical College in 1894.

Dr. OTTO FRANKENBERG of Columbus, O., died at his home, October 1, 1909, aged 63 years. He was a graduate of the Starling Medical College, in 1870, and for twenty years was a member of the faculty of that institution.

Dr. JUNIUS K. BATTLE of Eufaula, Ala., died at his home, September 28, 1909, aged 48 years. He was a graduate of the medical department of the University of Louisville, in 1883, and was a member of the Barbour County Medical Society, the Medical Association of the State of Alabama, and the American Medical Association.

Dr. CHARLES P. BEAMAN of Ithaca, N. Y., died October 6, 1909, aged 49 years. He was a graduate of the New York Homeopathic Medical College, in 1882, and was for many years official physician to the Cornell University athletic teams.

Dr. SWEZEY GILBERT HOPKINS of Yaphank, New York, died recently at North Falmouth, Mass., aged 68 years. He was a graduate of the Bellevue Hospital Medical College in 1869.

Dr. JOSEPH F. X. POITRAS of Brockton, Mass., died at his home, October 1, 1909, aged 43 years. He was a graduate of the Medical School of McGill University, in Montreal, in 1890. Shortly after graduation he moved to Marlboro, Mass., and then to Brockton. Dr. Poitras was one of the founders of the Brockton Medical Society.

Dr. ORSON VALENTINE THAYER of San Diego, Cal., died at his home, September 19, 1909, aged 86 years. In 1846 Dr. Thayer graduated at the Vermont Medical College, formerly at Woodstock, but extinct since 1856. He practised in San Francisco for thirty-six years and was a member of the San Francisco Medical Society.

Dr. WILLIAM B. ARTZ of Osage City, Kan., died at his home, September 24, 1909, aged 59 years. Dr. Artz was a graduate of the College of Physicians and Surgeons of Keokuk, in 1878. He was a mayor of Osage City for four years and councilman for six years.

Dr. DANIEL GARRISON died at West Collingswood, N. J., on October 4, at the age of 63 years. He was graduated from the medical department of the University of Pennsylvania in the class of 1880. He had resided in Pennsgrove, N. J., for more than thirty years.

Dr. HARRY D. NILES of Salt Lake City died at his home on September 28, 1909, of apoplexy, aged 53 years. He was a graduate of the Medical College of Ohio in 1880. Dr. Niles practised surgery in Salt Lake City for 24 years, and was at different times president of the Western Association of Surgeons and the Utah State Medical Association.

Dr. HOWARD SUMNER DEARING of Boston, Mass., died at Hollis, Maine, October 4, 1909, aged 52 years. He was a graduate of Dartmouth College in 1879 and the Dartmouth Medical School in 1882. Dr. Dearing was prominent in the medical department of the Massachusetts Militia for 25 years, holding all positions from hospital steward to colonel and senior surgeon of the State. During the Spanish War he was surgeon to the First Heavy Artillery. At one time Dr. Dearing was Professor of Clinical Medicine at Tufts College Medical

School. He was a member of the Suffolk County Medical Society, the Massachusetts Medical Society, and the American Medical Association.

Dr. J. B. Cowan of Lebanon, Tenn., died recently at his home. He was a graduate of the medical department of Vanderbilt University in 1881.

Dr. Samuel Carter Van Antwerp of Vicksburg, Michigan, died at his home October 5, 1909, aged 62 years. Dr. Van Antwerp was a graduate of the University of Michigan in 1872, and was the pioneer physician of Vicksburg. He was a member of the Kalamazoo County Medical Society, and the Michigan State Medical Society.

Dr. Henrietta Paine Westbrook of Philadelphia died at her summer home at Burrilville, R. I., on October 15, aged 74 years. Though a graduate of the Woman's Medical College of Philadelphia, Dr. Westbrook had never practised medicine, but gave up her life to literary work and was the author of many sketches and novels.

Dr. Rebecca Cooper Hallowell died at Haddonfield, N. J., on October 13, at the age of 77 years. She was graduated from the Woman's Medical College of Philadelphia in the class of 1878, and later acted as Medical Missionary for the establishment, on behalf of the Women's Matronal Indian Association, of a hospital at Adun Colentz, San Diego, California.

Correspondence.

FIFTEENTH INTERNATIONAL CONGRESS ON HYGIENE AND DEMOGRAPHY.

To the Editor of the Medical Record:

Sir:—On the invitation of the Department of State of the United States Government, the Fifteenth International Congress on Hygiene and Demography will convene for the first time on the American continent in Washington, D. C., from September 26 to October 1, 1910. Section III of this congress deals with the subjects of the hygiene of infancy and childhood; school hygiene. It is believed that this will be a meeting of the utmost importance. We take this means of requesting your readers to let us know of any pieces of original work which are being done bearing upon this topic.

A. Jacobi, *President.*
Luther H. Gulick, *Secretary.*
1 Madison Avenue, New York.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

OPENING OF THE SESSION—DR. MIERS ON STUDY—FEEDING PRISONERS WITH THE STOMACH TUBE—DEBASED AREAS IN LONDON—SANITARY DEPECTS OF GRAVESEND—A NEW EAST END HOSPITAL—HANBURY MEDAL—OBITUARY.

London, October 1, 1909.

This is the traditional opening day of the medical schools, when new students are supposed to enter for their first session, and on which the introductory lecture addressed to them has so long held an important place, though it has of late years been supplanted in some schools by other ceremonies, such as distribution of prizes, conversaziones. Then the end of the week is not propitious for the commencement of serious work, so that the introductory, where retained, is, in some cases, postponed until Monday next. At the London Hospital a reception of old students is to take place in the college library at 5 P.M. and a dinner at the Savoy Hotel at 7:30. At St. Thomas's a dinner at the Cecil is to mark the opening, and at Charing Cross the prizes are to be distributed by Sir Clifford Allbutt in place of Viscount Ridley, who was to have undertaken the task. At Guy's Sir Hector Cameron has promised to address the Students' Physical Society on some aspects of antisepticism. At University College Sir J. Tweedy is to give an address at the prize distribution, and at the Middlesex this function will be performed by Lieutenant Shackelton. The Women's School will be addressed by Mrs. Henry Fawcett. At St. George's Dr. H. D. Rolleston gives the address in the afternoon and the annual dinner is held at the Prince's Restaurant.

At St. Mary's Hospital prize distribution the students are to be addressed by Dr. H. A. Miers, principal of the University of London. This gentleman on Monday inaugurated the eighty-seventh session of Birkbeck College with an address, in which he said many things that will bear repetition if he cares to restate them to St. Mary's students. Remarking that every friend of popular education was proud of the work done by the Birkbeck, he mentioned a possible danger of the great facilities now freely offered to London students—that of forgetting that all these provisions were useless without effort on their own part—a danger of thinking education was a process of putting something into the student. A stimulus, he admitted, of a sort was felt in the shadow of an examination at every stage, and it was a melancholy reflection that if that were taken away a great number of English students would lose their chief incentive to intellectual effort. He advised them not so much to amass facts and acquire knowledge as to understand principles and acquire wisdom. If they mastered not the details, but the principles of a subject, they would do as much for their true education as any teacher, book, or examination could do for them.

Among the founders of the college was Francis Place, the radical tailor and friend of Jeremy Bentham and James Mill, who rose to play a large part in social reforms, and whose tale Dr. Miers told in the course of his lecture. He was born within a stone's throw of the college and spent his boyhood in sordid surroundings. After his marriage the weekly earnings of himself and wife did not exceed seventeen shillings, yet, said the lecturer, he managed to educate himself and become a man of great influence among his most intellectual countrymen. "It is surely appropriate that I, his great-grandson," added Dr. Miers, to the astonishment of the audience, "should congratulate the British institution upon the good work it has done."

The House of Commons has been amused day after day by talk about the horrors of the stomach pump. The Socialists seem to have taken up the cause of the suffragettes who have been refusing to eat in prison, and have therefore been fed with the tube. Having elicited this fact, Mr. Keir Hardie exclaimed "A horrible outrage!" and he has kept up questioning the Home Office since. He has also issued a statement to the public "concerning the horrible brutality of this proceeding," calling on "British men to think over the spectacle," and telling how "horrified" he was at the "levity" displayed by members when his question was asked and at the "scene" which he declares "has no parallel in the recent history of our country." He has since been writing to the press and describing as "torture" the method of forced feeding. This seems to be a political inexactitude. It can hardly be ignorance, as during "the scene" which so touched his tender feelings he was told that the treatment is that usual in hospitals and asylums when lunatics or feebleminded persons attempt suicide by refusing to eat. Most members of the House must know that there is no cruelty in forced feeding, and some doubtless must have heard of invalids who had learned to employ the stomach tube on themselves. Well might they laugh, then, when Mr. Snowden, in support of his leader, advised the Home Office to beg the Russian Government to send us over some "experts in the most brutal and up-to-date methods of barbarism."

It is now announced that the Women's Social and Political Union will prosecute the Home Secretary, the Governor of the Gaol, and the Medical Officer for the "unjustifiable assault" on the prisoners who were forcibly fed, and that the writs will be issued to-morrow, but it is not clear, in spite of Mr. Hardie's support, that either he or the union or any outsider has a *locus standi* in such a case.

Meantime, the Socialist members have continued to question the Government as to how medical treatment is carried out, whether the prisoners are put in irons to enforce it, and other absurdities, all evidently designed to annoy the authorities and to impose on ignorant people outside. It is therefore amusing to observe that every day up to date the Home Office has been able to reply that since the ladies have been fed with the tube their health has continuously improved.

The Medical Officer of Health for Southwark has given so serious a report on one district that the health authorities has appointed a special investigation com-

mittee. The district in question is said to be very debased, an abode of vice, crime, and immorality, in which the "scum of South London takes up its abode, generally for short periods." Many shocking details are added, and the Medical Officer of Health thinks the remedy is to clean the area, and until that can be done nightly inspection is absolutely necessary. He thinks all debased areas should be subjected to nightly inspection, and as he sees no prospect of the boroughs acting together, the County Council is the only authority capable of dealing with this matter.

Dr. R. J. Reece, in a report to the Local Government Board on the sanitary state of Gravesend, says the corporation should seek the advice of a competent engineer with a view to the abolition of the present system, the efficient sewering of parts of the town not properly sewered, and the efficient flushing and ventilation of existing sewers. Dr. Reece considers that the contents of the present cesspools must find their way into the river or remain in the chalk soil, to the danger of the water supply.

On Saturday the Lord Mayor laid the foundation stone of a new hospital for women and children of Eastern London. It is situated at Plaistow, opposite a smaller hospital, of which it is to take the place, and which was founded in 1888. It is to cost £16,000, and nearly £14,000 has been raised.

On Wednesday the sixty-eighth session of the School of Pharmacy was opened and the various prizes presented to the students. The Hanbury gold medal, accompanied by a check for £50, given every two years for original research, was received in person by Dr. Alexander Tschirch, "professor of pharmacognosy" in the University of Berne, whose paper on that subject was read for him in English by Professor Greenish, dean of the school, who had assisted in the translation.

A Coroner's inquest was necessitated by the sudden death last week of Dr. Eustace Rhodes St. Clair Corbin of Beckenham. He had accompanied a patient to a consultation with Sir John Tweedy and afterward to an optician's, in whose shop he fell down unconscious and died soon afterward. Dr. Florence Willey made a post mortem, and testified that there was extensive disease of the heart, which was the cause of fatal syncope. Verdict accordingly. Dr. Corbin was a University College student, where he took the Fellowes gold medals in clinical medicine and midwifery. He graduated M.B. Lond. with honors in 1886, and had been house surgeon at the hospital and demonstrator in the college.

Dr. J. Milson Rhodes of Didsbury, Manchester, died suddenly on Saturday night. He was an authority on many questions relating to the Poor Laws and Lunacy in their medical aspects. In his "Workhouse Dietaries" he put forth information of so convincing a kind that the Local Government Board was induced by it to institute an inquiry, which resulted in the removal of many anomalies to which Dr. Rhodes had directed attention. This work was followed by others on "Epileptics and Imbeciles," "Boarding Out of Pauper Children," "The Feeble-Minded and Epileptic," and numerous contributions to allied subjects. Dr. Rhodes was an Owens College student and took the double qualification of Edinburgh in 1874, following later with M.D., Brussels. He was a member of the Manchester Medical Society, the Economical Society, and the International Society of Public Assistance, Paris, to the conferences of which he contributed various papers. He suffered from cardiac weakness, for which he took strychnine. After a heavy day he took 10 minims of liquor, but as he thought it rather too much, took 2 drams of potassium bromide. His nephew, also a doctor, stated at the inquest on Monday that he died from a collapse, which both knew might have occurred at any time during the last two or three years.

Dr. Hubert E. J. Biss, who died on the 20th inst., aged thirty-seven, was a Cambridge graduate in arts (Nat. Sc. Tripos), 1896, and medicine, M.D., 1901. He had been demonstrator in biology and anatomy and assistant in the laboratory at Cambridge. Subsequently he held resident offices at Brompton Consumption Hospital and other institutions. He also took the D.P.H., and wrote on some sanitary questions in the journals, as well as diphtheria and scarlet fever, their pathology, treatment, etc. He was assistant editor of the *Medical Press*.

Dr. Thomas Watt, who died last week, was at one time Medical Officer at Howingham, near Malton. It was while acting as such that he became so interested with the housing of the rural population that he devoted himself to reform. At the funeral service on Monday there was a large concourse of the people, and addresses were given by his brother, the Rev. C. Watt, and Mr. Glassyer. Representatives were sent by the Independent Labor party, of which the doctor was one of the founders.

THE SIXTEENTH INTERNATIONAL MEDICAL CONGRESS.

(From Our Vienna Correspondent.)

CHRONIC PANCREATITIS—LEAD POISONING—ARTHRODOSIS—LUPUS ERYTHEMATOSUS—INTRANASAL DRAINAGE—LARYNGEAL CANCER—MUSEUM OF SAFETY AND SANITATION—SANITARY USE OF OZONE—PATHOLOGY OF NERVOUS DISEASES—TREATMENT OF PARALYSIS.

BUDAPEST, September 14, 1909.

MR. MAYO ROBSON of London drew attention to chronic pancreatitis as a clinical entity apart from gallstone trouble, and he also described the frequency of inflammatory enlargement of the common duct. He pointed out that chronic pancreatitis might persist long after the original cause had disappeared and might simulate cancer of the head of the pancreas and so terminate fatally under the impression that it was incurable, when as a matter of fact suitable surgical treatment was capable of curing the condition. Robson described the symptoms, the pathological condition, the causes, and the treatment of chronic pancreatitis and showed that the anatomical variations in the relations of the common bile duct to the pancreas and in the termination of the ducts had an important bearing on the etiology of the condition. He urged the importance of preventive treatment, such as the removal of gallstones before they had produced complications, and the treatment of duodenal ulceration by gastroenterostomy. If, after a fair trial of general treatment, not too long continued, the symptoms persisted and the signs of failure in pancreatic digestion and metabolism were manifesting themselves, the question of surgical treatment ought to be seriously considered, especially when the disease was associated with jaundice. He said that rational treatment should aim at the cause, whether that was gallstones, pancreatic calculi, duodenal catarrh, duodenal ulcer, alcoholism, or syphilis. Even in the absence of obvious removable causes he advocated efficient drainage of the infected bile and pancreatic ducts, either by cholecystotomy or cholecystenterostomy, preferably the latter. His experience had taught him that if the cause could be removed at an early stage an absolute cure was possible, and though complete restoration of the gland was not to be expected, an arrest of the morbid process might be looked for and the remaining portion of the pancreas would be able to carry on the metabolic, even if incompletely the digestive, functions of the gland.

Dr. Kenneth W. Goadby of Dublin described some animal experiments on the pathology of lead poisoning. The methods of infection were: Inhalation, feeding, and inoculation. The animals thus experimented upon developed signs of well marked lead poisoning, the ones inoculated exhibiting the most acute symptoms, the animals subjected to inhalations of dusty air held an intermediate position, and the ones fed on lead compounds showed the least sign of disease. The symptoms exhibited by the animals were in every way comparable with those of man, including wasting, paralytic symptoms, and mental symptoms. Careful histological examination was made of all the tissues of the animals, and in all cases where an animal had been poisoned by lead, minute microscopical hemorrhages were to be found in all the tissues examined. No degeneration was discoverable, but minute hemorrhages were found in the nerves supplying the paralyzed muscles, the paralysis evidently having been caused by the pressure of the hemorrhage and not by an early degeneration of the nerve. Microscopical hemorrhages were also found throughout the tissues of the brain, in no case of large extent, and nearly always quite microscopic in size. The various findings described by other observers of sclerosis and other pathological thrombi changes would seem to be the result of these minute hemorrhages.

Mr. R. Jones of Liverpool, discussing arthrodesis, said that the operation should never be performed on children under eight years, nor until all deformity had been corrected by wrench and tenotomy. It must not be performed if any hope existed of muscular recovery. It should be planned so as to avoid injury of

epiphysis and so that the bones lay in good apposition. Splints should be worn until consolidation is complete.

Mr. Morris of London, in discussing the treatment of lupus erythematosus, said that the disease appeared to be essentially a chronic inflammation of the skin, local in origin, and depending on a condition of the circulation which made the integument prone to vasomotor disturbance. This might cause a predisposition to toxic infection, but neither the fact of such infection nor its nature had been positively demonstrated. Each case must be dealt with according to its peculiarities. The treatment should be constitutional and local. Under the former head must be included careful regulation of the diet, so that the intestine might not be loaded with materials that might form a favorable soil for infection. Anything like coffee and tea, which caused flushing of the face, was contraindicated. Quinine was often useful. Locally, in the hyperemic stage, cooling lotions and ointments (calamine, subacetate of lead, etc.) should be applied. Ichthyol in the form of a lotion or an ointment was the most useful of local remedies. In chronic cases also the author had found the constant application of a strong solution of ichthyol the best remedy. Iodine liniment was also useful, in severer cases linear scarification, or light touches of the thermocautery often gave good results. In subacute cases the author had sometimes used high-frequency currents, and in chronic cases the Finsen light and the *x*-rays, with success. These agents are particularly useful in the later stages, when there is thickening of the integument.

Dr. Fletcher Ingalt of Chicago described his method of intranasal drainage of the frontal sinus, consisting of enlarging the nasofrontal duct by passing in through it a small steel probe—passing over this a hollow burr, operated by an electric motor, thus making a canal 6 mm. in diameter—placing in this canal a self-retaining gold tube which remained until the canal was lined with mucous membrane and therefore became permanent. Then at the end of three or four months, or any convenient time thereafter, the tube was easily withdrawn. Without criticising any other operation, on an experience based on over 30 cases, the author believed the operation safer than any other—believed it applicable to 95 per cent. of all chronic cases of frontal sinus empyema and that it would cure 95 per cent. of the patients operated on in from two weeks to six months.

Sir Felix Semon of London presented a contribution toward the diagnosis of laryngeal cancer and related and graphically illustrated those cases of malignant disease from his own practice, in which exceptional diagnostic difficulties were encountered, and in a number of which diagnostic mistakes were made. They amounted to 13 in a total number of 246 cases of malignant disease seen in thirty-three years' practice, and the author, after faithfully recording the salient features of each of them, exhorted in conclusion his younger confrères not to consider the early diagnosis of malignant disease of the larynx as exceedingly difficult, but to keep in mind such unusual features as were present in his series of cases.

Dr. H. Tolman, in a paper entitled "The American Museum of Safety and Sanitation," said that a conservative estimate of the number of annual accidents in the United States which resulted fatally, or in partial or total incapacity for work, was 500,000. Reckoning the wage-earning capacity of the average workman at $500 a year, there was a social and economic loss of two hundred and fifty million dollars a year. It was the opinion of the engineering profession that one-half of the accidents in the United States were preventable. The Museum of Safety and Sanitation would be the means of saving thousands of lives; would lessen the economic waste of accident cases brought before the courts; it would be an experimental laboratory for every industrialist in the country; through its own laboratories safeguards might be perfected for dangers and processes now without any known device; it would be an additional center for teaching the science and preservation of health, by the means of demonstrations in preventing diseases due to impure foodstuffs, bad ventilation, occupational dusts and poisons, infection, tuberculosis, and offensive trades.

Dr. Gilbert J. Fowler, in a paper on "The Sanitary Uses of Ozone," discussed the application of ozone to the purification of water and air in the light of the most recent developments. The purification of water was considered in reference to: Organic matter in solution and suspension, color, smell, taste, organismus, *e.g.* algæ, infusoria, bacteria, and metallic impurities. It was concluded that ozone treatment of water was to be recommended: (a) where adequate sand filters were costly to erect and difficult of supervision; (b) where the amount of organic matter in solution in the water was limited; (c) where the pollution was mainly bacterial and of an intermittent character; (d) where electrical power could be obtained cheaply.

Dr. B. Sachs of New York discussed the pathology of hereditary diseases of the nervous system. Instead of speaking of hereditary disease, it might be better to speak of family diseases, realizing fully that very few diseases were conveyed directly from parent to child, but that the morbid tendency existed in one or both parents which led to the development of a family disease. There was a very marked difference between the cerebral and the spinal groups. The family or hereditary diseases of cerebral origin were due to changes in the highest nerve elements, viz., the ganglion cells; the spinal hereditary affections were due largely to diseases of, or maldevelopment of, one or more systems of white fibers. The one exception to this group was the spinal form of progressive muscular atrophy, and that was only rarely inherited. The progressive dystrophies constituted a distinct group and were not of neural origin.

Dr. Robert W. Lovett of Boston discussed the treatment of paralytic deformities in children. There were varieties of paralytic deformity. These are seven: (1) Deformity due to simple gravity distortion; (2) to adaptive shortening and lengthening of soft parts; (3) to the contraction of non-paralyzed limbs; (4) distortion from weight bearing on partly paralyzed limbs; (5) deformity of the trunk due to effort to secure equilibrium; (6) bony deformity following persistent malposition, and (7) dislocation. The use of supporting apparatus was advocated from an early period for the purpose of preventing malpositions of the paralyzed limb. The treatment of paralytic deformity was discussed first, under the head of mechanical treatment, and, secondly, the operative, both supplemented by a third therapeutic measure, the development of the muscles by muscle training, massage, and electricity. Conclusions favorable to the performance of the tendon transference operation in suitably selected cases were presented. The results of a circular of injury sent out to the members of the American Orthopedic Association were given, the conclusions from this being that the operation was on the whole useful and that periosteal insertion was preferable to insertion of tendon into tendon. The conclusions were presented that the after treatment was fully as important as the operative. The summary of the paper called attention to the fact that the treatment of paralytic deformity should consist of a combination of the three methods and that the operative should not overshadow the others, and that the operation of tendon transplantation in properly selected cases was to be regarded as a useful and satisfactory one.

Dr. Nagelschmidt of Berlin read a paper before the Section on Therapeutics on the procedure to which he himself had given the name of transthermia, by means of which he had been able to transmit a greater or less degree of heat into the deeper tissues. The method was a variation of the high-frequency current. The current differed from the D'Arsonval in that the electrical oscillations were almost without pause, of equal amplitude, and of a much lower tension. By this a new action was obtained. These waves had the power to flow from one pole to the other through the organism and to raise the temperature along their entire course. He demonstrated this by cooking a piece of meat between the poles of the battery. The deep action was shown to be as marked as the superficial. Different substrata warmed up to different amounts; distilled water warmed but little, physiological saline more; a 1.5 per cent. salt solution still more, and blood serum and corpuscle emulsions most of all. Among animal tissues the skin, besides being the most difficult of penetration, was the easiest to warm up. Following this in descending ratio came bone, muscle, fat, and nerve. The amount of the heat production was regulated by the subjective sensation of warmth, and the objective feeling of the skin to the fingers of the physician; when under a general anesthesia, by measuring the current and the surface of the electrode, and especially by placing a small thermometer deeply in the tissues. Tumors both superficial and deep could be coagulated by

this method. When a deep action alone was desired this could be produced by applying cooled electrodes to the surface. In this way deep-seated tumors could be treated without injury to the skin and without opening of blood-vessels. The method had proved itself of value in tumors, neuralgia, rheumatism, especially lumbago, various joint affections, gout, and particularly in asthma.

Dr. Josef Fabricius of Vienna said that disease of the appendix was often mistaken for gynecological troubles. When the appendix was exceptionally long or in an abnormal position it might descend into the true pelvis, and disease of that extend to the adnexæ and *vice versa*. Acute appendicitis might be mistaken for acute salpingitis, oöphoritis, acute inflammatory pyosalpinx, perforation peritonitis following rupture of a pyosalpinx, or an ovarian abscess, extrauterine pregnancy, or a twisted pedicle of an ovarian cyst or tumor of the tubes. Tenderness over the cecum was not in itself a definite sign of appendicitis, vaginal examination being also of value. The adnexæ reached to the cecum only when they were large or the uterus stood very high up. In appendicitis the tenderness first appeared over McBurney's point, in pelvic disease near the uterus. Swelling of the appendix might occur during infectious diseases. Appendicitis coming on near the beginning of pregnancy might result in an abortion. In such cases the appearance of a resistance in the right pelvis might suggest an extrauterine pregnancy. Chronic appendicitis came into gynecology frequently. It might cause pain, even light colic, at the time of menstruation, though acute appendicitis he had not seen as a result of the menses. In nervous people neuritic symptoms suggesting hysteria or epilepsy could be produced. It could have a bad influence over pregnancy, so much so that it was advisable to remove the appendix at that time. It could produce malpositions of the uterus. The author advised orientation of the uterus in every laparotomy for appendicitis, and if malposition was found correction of the same. Chronic appendicitis, by interfering with the tubes, might cause sterility or lead to an ectopic pregnancy. Intestinal obstruction might be produced by the bands of adhesions between the appendix and the adnexæ. In case of chronic appendicitis one often found a symptom complex consisting of anemia, gastric atony, and nervousness, so that appendectomy did not cure the patient until these symptoms had been treated properly. Once the author had seen abdominal actinomycoses and once ovarian tuberculosis following chronic appendicitis. Disease of the appendix might be transferred to the adnexæ, and *vice versa*, or disease of the two might occur concomitantly and independently. The speaker said that in every case where there was any suggestion of appendical disease he advised laparotomy.

Progress of Medical Science.

Boston Medical and Surgical Journal, October 7, 1909.

A Study of the Reticulated Red Blood Corpuscle by Means of Vital Staining Methods; Its Relation to Polychromatophilia and Stippling.—J. B. Hawes, 2d, reaches the following conclusions: (1) The condition known as stippling and that known as polychromatophilia, as described in his paper, are probably but different forms of the same process. (2) Reticulated red cells, "*les hematies granuleuses*" of Chauffard and Feissinger, as shown by simple vital stains, either in temporary or permanent specimens, correspond to the stippled or polychromatic cell as seen in the fixed preparation, and are due to the same cause. (3) Owing to the greater delicacy of the vital staining method, the reticulated forms will always be found in considerably greater percentages than stippled or polychromatic cells. (4) All these phenomena are evidences of cell regeneration, and are indications of the activity of the blood-forming organs. (5) Reticulation forms occur in normal blood in slightly less than 1 per cent.; in certain pathological conditions they may be present up to 22 per cent., according to some authors, or, according to others, up to even 65 per cent. (6) A study of the reticulated forms in pathological conditions of the blood, especially in secondary anemias, is of value in diagnosis, prognosis, and treatment. In benign hemorrhages causing secondary anemia the percentage of reticulated forms was very high and the percentage of polychromatophilia and stippling was much increased. In extreme anemias, as in hemophiliac cases, the reticulate percentage was below even normal limits, while practically no stippling nor polychromatophilia was found. In prognosis a large increase in reticulated forms in both primary and secondary anemia is a favorable sign that the blood-organs are actively at work.

Varicose Veins of the Leg.—H. M. Chase discusses the physiology of the condition, factors in preserving normal circulation, methods of examination, and treatment. The latter may be classified as follows: (1) Medical, to regulate and improve dietetic functions, to stimulate cardiac force and increase the tone of the vessel walls, to moderate or delay fibrous or atheromatous changes. (2) To continue normal muscular actions which in contraction will give a centripetal direction to the venous blood and aid in maintaining and continuing the velocity of the blood current. (3) Local treatment for varying conditions of tissue change resulting from venous stasis, such as eczematous conditions, serous and hemorrhagic blebs, active serous exudation, local fibrosis, edema, ulceration, and necrosis. (4) Mechanical support of the superficial blood-vessels which will direct a large portion of the venous blood through the deep veins, will relieve tension on the superficial veins, and permit a restitution of the elasticity of the subcutaneous tissue, diminish the pressure due to venous engorgement in the superficial veins, and permit a greater capillary velocity in the blood current. (5) Surgical measures. The author then elaborates the principles and details of treatment as suggested by this classification. He says that the treatment of varicose veins resolves itself largely into the application of mechanical principles which will control abnormal circulatory conditions.

A Case of Arteriovenous Anastomosis for Senile Gangrene.—An operation was done by J. C. Hubbard in a negro aged seventy-seven years. The site of the procedure was in Scarpa's triangle. Details are given. The results showed that the circulation in the foot was sufficiently improved to restore the original color in the affected extremity all but the toes. Edema of the leg, which was slight at first, later became excessive, making the leg seem to the patient full and stiff. Coincident with this edema, pain, which had decreased after the operation, became the most prominent symptom. The author asks was this pain due to pressure on nerves already enfeebled or was it due to progress of the nerve changes started by impending gangrene and not stopped by the apparent improvement in the circulation? The case demonstrates, he thinks, that an anastomosis can be performed in man which will remain patent for some time. The case teaches also that a single anastomosis between the artery and the vein renders the return of the venous blood too difficult. A complete reversal of the circulation is therefore to be recommended. It remains to be seen whether this will prevent edema, and, if so, the pain. In this particular case the pain became so severe that amputation above the knee became necessary. After the operation the tourniquet was loosened in order to test the anastomosis. From the femoral vein in the stump, red arterial blood spurted. There appeared to be no narrowing of the vessel judging by the size of the blood stream.

New York Medical Journal, October 9, 1909.

A Danger-Free Method of Using Freshly Prepared Virus (Virus Fixe) from the Brain of the Hydrophobic Rabbit.—The paper of F. Proescher is a review of recent literature along the line suggested by the title. *Virus fixe* is virus made from the dried rather than from the fresh cord. The redrying of the cord does not, according to Pasteur, influence in any manner the virulence or quality of the virus, but simply diminishes the amount in the desiccated cord. Statistics indicate that the safety of the immunization increases in direct proportion to the virulence of the material injected. At the present time probably 15,000 persons have been immunized with *virus fixe*. It is impossible to tell by animal experiments whether a certain virus is of the street (undried) or fixed variety. The practical value of using fresh *virus fixe* for treatment depends on a single factor, and that is that the *virus fixe* must be absolutely atoxic and avirulent for the human being. At the present time it is impossible to determine on account of the small dosage used, whether the *virus fixe* employed in the various laboratories has these qualifications. Careful investigations and experiments are necessary to determine the virulence for man of the street virus after passage through a single rabbit. It is not yet known whether the passage of the street virus through a single rabbit will render it avirulent for the human being. It is not necessary any more to dry the spinal cord, and at the same time the more virulent brain tissue can be used, thus eliminating the tedious and difficult dissection of the spinal cord. The using of fresh *virus fixe* is very

advantageous to both physician and patient, as it offers greater security than the old Pasteur method, due to the giving of fresh *virus fixe* on the first day, thus losing no time in the immunization with a virulent *virus fixe*, which all authorities agree does not give any protection, but affords time for possible development of rabies. By the method described in this paper, the immunization time is shortened two-thirds, and both trouble and expense are saved.

Isolated Fracture of the Transverse Process of a Lumbar Vertebra.—The patient of S. Lange was a man of 50 years who strained his back while lifting. Coming under observation some four months later, after considerable pain, an area of tenderness was found just to the left of the last lumbar vertebra in the angle between the crest of the ilium and the spine. The *x*-ray revealed what was undoubtedly a fracture of the left transverse process of the fifth lumbar vertebra. The process appeared to be tilted up, and there was an irregular fissure separating the tip of the process from its base. The author also reports a second case of a man of 35 years. Here the injury was received from a rapidly revolving crank handle. The *x*-ray showed a fracture of the right transverse process of the first lumbar vertebra, with some upward displacement of the broken fragment. These cases are very rare. Only three had been reported up to a year ago. The frequency with which the symptom, chronic sacrolumbar pain, is met with and the difficulty so often offered in the recognition of its cause lends considerable clinical importance to this type of fracture. If the fracture is unrecognized at its inception, and many such fractures are undoubtedly passed over as "sprains," nonunion or delayed union will follow, due to the fact that the loose fragment will move with every movement of the body. The pain may thus become chronic and persist for a considerable period. In some cases the patient will incline the body toward the side of the fracture. Continuance of this posture over a period of time may lay the foundation for a persistent scoliosis. The diagnosis is based upon the history of the accident, tenderness to pressure over the fracture, slight muscular rigidity, and pain of varying severity which is increased by movements of the trunk, especially walking and stooping, and relieved by lying down. If the case is seen later the *x*-ray alone will establish a diagnosis. Although the fracture *per se* is of minor importance, its recognition is of great prognostic moment in that the more serious condition, such as tuberculosis and arthritis deformans of the spine and sacroiliac joints, are thus ruled out. The recognition of this fracture has furthermore some medicolegal importance, owing to the peculiar nature of the causal trauma and the symptoms.

A Practical Test for Indican in Urine.—The following method is commended by F. C. Askenstelt: To 10 c.c. of urine in a test-tube add 10 c.c. of the ferric chloride solution and mix by inverting the tube once; then add quickly 8 c.c. of chloroform, and extract the indigo in formation by shaking the tube 400 times, holding it in a horizontal position. After this let the chloroform fall to the bottom of the tube, then pour off most of the supernatant fluid, fill the tube nearly full with water, invert it a few times to wash the chloroform, and let this again precipitate in the tube, and pour off most of the water. Repeat twice this process of washing, taking care that no chloroform escapes with the wash water, and allowing not more than 2 or 3 c.c. of the last wash water to remain over the chloroform. Now add from 13 to 15 c.c. of alcohol and mix by shaking. A clear blue fluid should result. If hazy, add one or two c.c. more of alcohol until the fluid clears up. Compare the color of this fluid with an equal quantity of a standard solution of indigo blue in the second test-tube by holding the two test-tubes in front of a white surface. This standard solution is made by pouring into the empty second tube a quantity of water equal to the amount of the fluid in the first tube, and then dropping the stock solution of indigo blue into the water, inverting the tube after each drop, until both solutions have the same amount of blue color. If this requires four drops of the stock solution the percentage is 0.0004; if five drops, 0.0005; if six drops, 0.0006, etc.

Journal of the American Medical Association, October 9, 1909.

Diet in Typhoid Fever.—W. Coleman believes that the solution of the essential problems of the typhoid fever diet will be found in the answers to two questions: 1. Shall the typhoid fever patient be given enough food to meet his energy requirements? 2. How much food may be considered necessary for this purpose? The starvation diet, formerly the accepted process for all fevers, has lingered in typhoid, but the practice has gradually advanced from the 300 calories in 24 hours of Graves and Trousseau to the milk diet of Flint furnishing 1,400 calories and the 2,000 calories diet of Bushuyev. There is strong experimental and clinical evidence in favor of giving the typhoid patient sufficient food to meet his energy demands without overfeeding or improperly feeding. Partial starvation lowers the resisting powers. The emaciation which is so characteristic of the disease is, Coleman believes, largely due to the pyrexia and the toxins, though it is not known definitely how these latter act. Shaffer and Coleman have found in their cases that the losses due to these causes can be prevented by a high caloric carbohydrate diet, and the most potent factor of the emaciation is therefore partial starvation. A normal man at ordinary rest requires about 33 calories per kilo of body weight each day, and if we add to this the 25 per cent. addition to make the febrile increase which, according to Krehl, is demanded in typhoid, the patient requires 41 calories per kilo of body weight, which for a man weighing 150 pounds would make a minimum diet of 3,000 calories per diem. Coleman has worked out the diet, which consists in the main of milk, cream, milk sugar, and eggs, with the addition of small amounts of stale bread or toast, with butter *ad lib.* The daily quantities were about 1½ quarts of milk, 1 to 2 pints of cream, from ½ to 1½ pounds of milk sugar, and from 3 to 6 eggs. The use of each of these remedies is explained and their use, and the reasons for their use. The milk sugar and cream can be given in the form of ice cream, in part at least, or with the eggs in the form of custard. The food has been given at two-hour intervals, except that the patient has not been wakened at night. The greater the variety and the more palatable the dishes, the more contented the patient. Meat and meat juices are prescribed by him in the diet and limited during convalescence. The amount of food will, of course, vary with different patients, but may be calculated on the basis of 40 calories per kilo of body weight *per diem*.

Intradural Tumor of the Cord.—J. Grinker, after remarking on the still sparse number of successful operations for intradural tumor of the cord, reports in detail a typical case in the upper dorsal cord, successfully operated on to the extent of complete restoration of sensation and partial restoration of motion, both of which had been abolished. The case resembles somewhat the typical first case of Horsley, and the tumor was of the same nature—a fibromyxoma. If the diagnosis had been made earlier, before degeneration had occurred in the motor tracts, it is probable that the success would have been complete. The reasons why so few recoveries are thus far recorded, that have been given, are that spinal tumor is not easy to diagnose or localize, and failure of operation usually means death; also the discovery in many cases that the tumor is inaccessible, and, further, that in any case the danger to life during and after operation is very great. While not underestimating these objections, Grinker is still of the opinion that an exploratory laminectomy is to be recommended, even with only a probable diagnosis. The patient should be told that inaction would be almost inevitably fatal. "In spite of the great activity displayed in this branch of surgery during the last ten years, the total number of cases with operations up to date has not exceeded 150. And of this number the percentage of recoveries has only risen in the hands of the most expert surgeons when working conjointly with neurologists."

Vulvar and Vaginal Neuritis and Hyperesthesia.—I. S. Stone calls attention to certain neglected disorders of the genital tract, and especially to certain nerve affections, neuritis, and hyperesthesia of the vulva and vagina, which are not sufficiently recognized by the average practitioner. The patient is generally a neurasthenic or neurotic, and is usually suffering from associated disease, which is often due to impaired function rather than to organic change. There is tenderness and occasional swelling of the parts, and painful micturition. They are usually treated for some slight apparent erosion, and Stone believes that the pain in cases of urethral caruncle is due to this cause, rather than to the caruncle itself. He has often seen such caruncles removed without relief, and says that unless there is associated cystitis the failure is generally due to neurasthenia. It is not always possible at first to distinguish between cases of hyperesthesia and neuritis, but it is comparatively easy if one is accustomed to distinguish these in other parts of the body. The diagnosis between these two, however, is not absolutely necessary, and it is also hard to say just which part of the organs is the seat of the disease. He finds that the sensitive area is usually about the vestibule or introitus. Occasion-

ally he finds it on or near the cervix. Two illustrative cases are reported. When the diagnosis has been once made the treatment becomes a matter of simple attention to the general health of the patient, the use of emollients, or drying powders, and the avoidance of all irritating applications. It should be remembered that any fluid may cause burning and smarting if there is a neuritis, and tender surfaces should be protected as much as possible.

Intestinal Autointoxication and Ear Disease.—J. H. Stucky argues for the recognition of autointoxication from the intestines as a cause of ear, nose, and throat disorders. Since in the eye we may have obliteration of function and toxemia, he asks, why may not we for the same reason have a similar condition in the ear? That we do meet toxemia of the auditory apparatus he says he has frequently demonstrated. In this class of cases we have some disorder of the nervous, digestive, excretory, or circulatory systems that exaggerates a comparatively trivial irregularity of the ear into serious deafness. Labyrinthine hyperemia is often caused by alcohol, gout, rheumatism, and certain drugs, and a hyperplasia of the labyrinthine capsule and certain systemic conditions, like gout and lithemia, due to a toxemia which he has shown to be of intestinal origin, have also a large causative influence. If gout and lithemia can cause ankylosis or trouble elsewhere in the system, why not in this place? He agrees with good authorities that there can be no doubt that the general constitution of the patient furnishes the main basis for the etiology of otosclerosis, and he has often found in diseases of the middle and internal ear and accessory sinuses of the nose, marked evidence of toxemia of intestinal origin, as shown by the excess of indican in the urine, and when this condition was relieved there was marked betterment or entire relief of the symptoms. He does not believe that every functional disease has a structural derangement to account for it. He has seen gastrointestinal disorders severe enough to destroy life without leaving any evidence of inflammatory elements. Imperfect nutrition or overnutrition and defective elimination may produce the toxin requisite for these effects, and the result is the toxemia showing itself in obscure neuroses of the eye, ear, nose, and throat, as well as other evidences of systemic poisoning. He promises in a subsequent paper to give more in detail the specific manifestations of these pathological conditions, the treatment employed, and the results obtained.

The Cause of Pellagra.—C. C. Bass gives an account of experiments made to test the Wassermann reaction in pellagra. The technique followed was the original Wassermann, except that lecithin was used instead of syphilitic liver extract. The hemolytic serum used was sheep corpuscles, serum of sensitized rabbit inactivated, a temperature of 56° C. for thirty minutes, and guinea-pig serum for complement. The patient's serum was inactivated before being tested. All six cases gave strong positive reaction. All the patients gave negative histories for syphilis: three were the mothers and one was the father of healthy children. One of the tests was made on blood taken twenty-four hours after death, and is, therefore, not to be thoroughly relied on. One patient denied eating corn-meal, though the diagnosis of pellagra seemed correct. Since the Wassermann reaction seems to be limited to protozoan diseases except in a few cases of advanced tuberculosis and leprosy, the results of these experiments, so far as they go, would seem to favor the protozoan rather than the corn-meal theory of the etiology of pellagra. The reaction may be of service in the diagnosis of earlier mild cases, and this study adds another disease to be considered in interpreting a positive Wassermann reactions, *i.e.* Bass' results are confirmed by a larger series of experiments.

Tuberculosis.—P. H. Ringer reports a case of renal tuberculosis occurring in a patient after severe exertion in building a house, and terminating in acute miliary tuberculosis within a year. The chronological order of events seems to have been as follows: An old healed apical tuberculosis, only discovered at autopsy; mobilization of the bacilli, probably due to violent physical effort; lodgment of bacilli in the right kidney, with establishment of renal tuberculosis and bladder symptoms; spread of infection to left kidney; breaking down of areas in the right kidney and discharge into a vein, giving rise to general dissemination throughout the lungs, and doubtless throughout the nervous system as well. The special interest in the case is its illustration of the relations of cause and effect in the revival of the disease by immobilization of the bacilli by physical strain, and their temporary halting place in the right kidney before spreading to the body at large.

The Lancet, October 2, 1909.

Hysterical Deafness Treated by Suggestion.—Case reported by P. M. Yearsley and H. E. Wingfield. The patient was a woman of 37 years. Nothing noteworthy was found on examination. The functional tests were somewhat conflicting in their results. Apparently, she was quite deaf. She was placed under the immediate care of Dr. Wingfield, who saw her on nine different occasions. At the first treatment her hearing returned for about two hours after she had left the doctor's office, but her deafness then returned. On the third occasion she said she could hear quite well, but the moment she heard she said she forgot what was said to her. Later, after all the sittings were over, she relapsed into her original condition. The authors comment on the rarity of these cases, but say that suggestion has been known to be successful in some cases, and that the case here considered certainly appears to have been one in which hypnotic treatment would have been successful had not circumstances prevented a longer trial.

Pathology of Lead Poisoning.—K. W. Goadby and F. W. Goodbody discuss the various modes of lead poisoning and the symptoms produced thereby. They conclude that the essential and primary action of lead intoxication is the production of minute and microscopical hemorrhages in various portions of the body, including the nervous system. That the clinical symptoms of lead palsy and its good prognosis when treated early are explainable by the presence of minute hemorrhages in the peripheral nerves. The pressure of these minute hemorrhages in the nervous system also gives an explanation of the varied pathological findings of many previous workers.

The Theory of Vision.—The paper of F. W. Edridge-Green is an elaboration of the points comprised in the following assumptions: (1) that the cones of the retina are insensitive to light, but sensitive to chemical changes in the visual purple. Light falling on the retina liberates the visual purple from the rods and it is diffused with the fovea and other parts of the rod and cone layer of the retina. The decomposition of the visual purple by light chemically stimulates the ends of the cones (probably by the electricity which is produced) and a visual impulse is set up which is conveyed to the brain by the fibers of the optic nerve. (2) That the visual impulses caused by the different rays of light differ in character just as the waves of light differ in wave length. Then in the impulse itself we have the physiological basis in the sensation of light and in the quality of the impulse, the physiological basis of the sensation of color. (3) That the quality of the impulse is perceived by a special perceptive center in the brain within the power of perceiving differences possessed by that center or portions of that center. According to this view, the rods are not at all concerned with transmitting visual impulses, but only with the visual purple and its diffusion.

British Medical Journal, October 2, 1909.

Uncured Rice as a Cause of Beriberi.—W. G. Ellis relates his experience in one of the hospitals of Singapore in regard to the effect on patients of diets of cured and uncured rice respectively, in addition to other foods. The matter was tested out in various ways, and it was proved to the author's satisfaction that uncured rice was the cause of many cases. Certain facts of interest in the general management of beriberi cases are added, one being that the return of the knee jerk in recovering cases may be delayed for years. The rice preferred by the author is that grown in Spain. It is soaked in water for forty-eight hours, the water being once changed, then placed in boilers and steamed (not under pressure) till the grains burst, generally a matter of from ten to twelve minutes. It is then sun-dried and afterwards goes through the mills, being husked in the ordinary way.

Note on Formalin Iodine Catgut.—This method of preparing catgut is preferred by F. J. Steward, who steeps the commercial formalin catgut in small skeins in 1 per cent solution of iodine in water for ten days. This is an extremely simple method, makes a strong suture, is very resistant and smooth, uniform in diameter, elastic, and easy to handle.

A Plea for a More Living Pathology.—The paper of H. Sainsbury is hard to abstract, but interesting to read. The object of an autopsy is not merely to find what lesion a patient died of, but why he died from it. This is perhaps a matter of words, but it is also a change in our viewpoint. We should look at life rather than death. The author does not refer to cases in which the lesion directly incapacitated [illegible] vital [illegible] as a hemorrhage into

the medulla, etc., but rather to fatty, fibroid, caseous, and calcific lesions. Under these latter conditions the end often comes suddenly. Life is an overcoming of momentum against resistance. When an organ partly dies as a cirrhotic liver or kidney, in which a tissue of a lower order replaces true secreting glandular tissue, the new fibroid elements may be said to add themselves to the internal resistance of the body. The attention of the autopsy student should be more directed to the compensatory powers of nature, as that of the heart, for instance, against increased capillary resistance, the vicarious workings of functionally allied parts, anastomotic adjustment, etc. We should determine not only where the body was unsound, but also where it was sound. Now, in doing this we should fall back on the history of the case during life. In such a way we shall learn just how much the damaged organ preserved its functional capacity. We shall endeavor to demonstrate the interaction of living parts. The toxemias will not lend themselves exactly to this associative illustration without the aid of the chemist. Toxemias do not always cause the same symptoms in the same class of disease, *e.g.* a granular kidney may cause coma, convulsions, uncontrollable vomiting, or diarrhea. The disease germ is in a sense *sui generis,* and therefore not capable of placing in the same class with those morbid sequences which we have been considering. It is a cause of disturbance, as a mechanical injury, exposure to heat, the incidence of a poison are causes of disturbance—the disturbance once set agoing, the lines of propagation depend upon the structure of the fabric disturbed. It is the potency of the germ that we want, and we have reason to hold that this potency has less relation to the form of the germ than to the intrinsic qualities of its protoplasm—namely, its powers of elaborating a virus. The germ castigates less as rod or flagellum than as toxin; the morphology of the germ, therefore, should be supplemented, as far as possible, by endeavors to demonstrate the chemical nature of the poison carried and the direction and intensity of its working. The same principles, therefore, will guide us in the demonstration of the germ as of the morbid tissue; we shall aim at exhibiting its dynamics as a toxifier.

Berliner klinische Wochenschrift, September 20, 1909.

Arteriosclerotic Variations in Blood Pressure of the Individual.—H. Engel says that the diagnosis of the early stage of arteriosclerosis stands on a weak foundation, especially as regards to objective symptoms. The increase of blood pressure is of but little value, as it also occurs in heart disease, nephritis, etc. In arteriosclerosis, however, the process is usually not quite symmetrical, more atheromatous patches occurring in one vessel than in another. As the blood pressure is dependent upon two factors, heart strength and arterial resistance, differences in the caliber of different vessels will cause the pressure in the different arteries to vary. Careful comparative blood-pressure observations of the two arms will frequently demonstrate a difference of from 5 to 15 mm. pressure between the two sides in cases of arteriosclerosis. Such a difference is an important diagnostic sign. These differences must, however, be constant, and observed at a number of examinations. A single reading is liable to error. This sign is also of value in differentiating a primary arteriosclerosis from a sclerosis secondary to nephritis, as in the latter case the variation between the two sides does not occur.

Münchener medizinische Wochenschrift, September 21, 1909.

The Inheritance of Syphilis Based on Serological and Bacteriological Researches.—K. Baisch has carried out a series of experiments to ascertain the truth of the facts concerning the inheritance of syphilis. His method consisted in examining the mother, the placenta, and the fetus in cases of miscarriage, both by searching for spirochete and by seroreactions. In all, 140 cases were examined. From the experiments the following conclusions were reached: To ascertain the laws of the inheritance of syphilis the Wasserman reaction alone is insufficient; it must be combined with bacteriological examinations of the placenta and fetus. With negative reaction in the parents an absence of spirochete is also necessary, in a partially macerated fetus, to rule out syphilis. The hemolysis inhibiting substance is not passed through the placenta from mother to child or *vice versa.* The appearance of the hemolysis hindering substance is dependant upon the presence of spirochete in the organism. The cause of premature death and maceration of the child is syphilis in 80 per cent. of the cases. In the other 20 per cent. twists in the cord, malformations, nephritis, or possibly tuberculosis are responsible. The typical habitual abortion during the first four months does not belong to the symptomatology of syphilis. In the neighborhood of 75 per cent. of the mothers of syphilitic infants show either no or indefinite signs of syphilis. If the mothers of syphilitic children give positive reactions, they are truly syphilitic, even if clinically healthy. Also, mothers who give negative serological reaction are in all likelihood infected. Here we are dealing with an inhibitor of the reaction. The Colles' law, which declares the immunity of the mothers of syphilitic children, and Profeta's law as to the immunity of children of syphilitic parents are explained in that the mothers and children are resistant to syphilis because they have been in reality already infected. Colles' law has no exceptions. The best chances for healthy children of syphilitic parents are given by a systematic and energetic course of specific treatment before and during pregnancy.

Investigations into the So-Called Salt Fever and the Chloride Excretion in Infants.—Friberger discusses the results obtained by Meyer and Rietschl in producing a rise of temperature in infants by giving sodium chloride by mouth and subcutaneously. In an attempt to confirm the work he was unable to obtain anything resembling the regularity of results reported by the Berliners, either in healthy or ill infants. Distinctly larger doses of salt were required to cause the reaction when given *per os* than when given hypodermically. Metabolic investigations varied to such an extent that no conclusions could be drawn. It was noticed that the sodium chloride given by injection was excreted more slowly than when administered *per os.* Investigations of the subcutaneous tissue at the site of the injection a few hours later showed a collection of lymphocytes, large mononuclears, and some polymorphonuclear cells. It is therefore possible that the salt fever is due to the mechanical trauma at the point of injection, and not to any constitutional action of the salt.

Study of Prowazek's Trachoma Bodies and Their Diagnostic Significance.—Grüter investigated fifty cases of trachoma and many others of acute or chronic follicular catarrh, some springtime catarrhs, and a few others eye diseases and normal patients. Of the 50 trachoma cases, 31 showed the picture of the acute disease, with profuse discharge. In 21 of these Prawazek's bodies were found. The number varied greatly in individual cases. Chronic cases treated with astringents gave consistently negative results. The bodies were found most frequently in the cases at the height of the disease, with profuse discharge. In nine acute untreated cases the results were negative. Examinations of the fibrous trachomas and the cases without trachoma were in every case negative. An absolutely definite indication is given only in those cases in which the Prawazek's bodies are found. A negative finding is not definite.

Scoliosis Following Infantile Paralysis.—M. P. Desfosses advances the theory that the cause of scoliosis is not osseous, but is due to a primary atrophy of the muscles of the back, accompanied by atrophy of the vertebræ. One of the principal causes of scoliosis is infantile paralysis, affecting the muscles of the thorax and lumbar region. The musculature of the back is very complex, very difficult to study in its different groups, and hence not well understood. There is a functional independence of the dorsal and lumbar regions. Infantile paralysis affecting the thoracic region will produce a scoliosis with the convexity toward the healthy side, while paralysis affecting the lumbar region will give a curvature with convexity toward the paralyzed side. Consequently, a paralysis of dorsal and lumbar region at once will give a double curvature.—*La Presse Médical.*

Difficulties of a Second Cesarean Section Repeated in the Same Woman.—A. Brindeau enumerates the possible complications of cesarean section that may render a second section more difficult and dangerous in the same woman. Several operators have repeated the operation one or more times in the same woman. The difficulties are hernia and eventration which rarely occur; adhesions; thinning of the uterus at the point of the cicatrix; and adhesions of the placenta to the cicatrix. Adhesions are quite frequent; they may be so slight that they are easily separated, or so firm that it is impossible to enter the uterus without opening the peritoneal cavity. The intestines may be involved in the adhesions, or they may simulate ventrofixation. The uterine wall may be so thinned and friable that the removal of the uterus becomes necessary. Adhesion of the placenta over the cicatrix is a rare complication.—*L'Obstetrique.*

Book Reviews.

Semmelweiss. His Life and His Doctrine. A Chapter in the History of Medicine. By Sir William J. Sinclair, M.A., M.D.; Professor of Obstetrics and Gynecology in the University of Manchester, Manchester; at the University Press, 1909.

While something of the story of Semmelweis's struggle to convince an unbelieving generation of the true nature of puerperal sepsis is known to most medical men, the full greatness of his intellect and tragedy of his life are probably but seldom appreciated. The book in which he finally collected the evidence of many years' observation and experimentation, and which was his culminating attack on those who opposed his doctrines with a rancor that is hard to comprehend to-day, had until very recently long been inaccessible even in German. Under the auspices of the Hungarian Academy of Sciences the collected works of Semmelweis were republished in 1905, but until the appearance of the present volume English readers have had little or no opportunity to familiarize themselves with the actual contents of his writings, and in particular of the most important, entitled "Die Aetiologie, der Begriff, und die Prophylaxe des Kindbettfiebers," a volume of over five hundred pages published in 1860. Sir William Sinclair has fulfilled the office of biographer and commentator with much judgment, and tells the story of Semmelweis's life and epitomizes his labors with sympathy and understanding. That he ascribes what is perhaps undue importance to the part played by some of his own compatriots in the final triumph of the teaching of the Hungarian obstetrician is natural enough, but it is a little hard to forgive the somewhat disparaging manner in which he speaks of the efforts of Oliver Wendell Holmes in the same direction, though the author's phrase that "If Semmelweis could have written like Holmes his 'Aetiologie' would have conquered Europe in twelve months" is a gracefully expressed tribute. For medical men of all ages no more inspiring reading can be suggested than the well-known lives of Pasteur, Helmholtz, and Huxley, and the present life of Semmelweis may well be added to this list.

The Errors of Mind Healing. Compared with the Miracles of Christ and His Disciples in the Healing of the Afflicted, as Viewed by a Physician. By Reinhold Willman, M.D. St. Joseph, Mo.: The Advocate Publishing Company, 1909.

The clergy and laity having entered the medical domain as healers, the author of this small publication, apparently in self-defence, has carefully reviewed the Scriptures and finds, from that authority at least, that they have not a leg to stand on. His book is replete with Scriptural quotations to this effect, which he intimates will be of service to the busy doctor whose knowledge of the Scriptures, unfortunately, may not be so profound as that of his materia medica. They may also be perused with profit by the lay reader. The author's descriptions of disease, however, embodied in the book seem to us an unnecessary part of it for the medical reader, and altogether too technical for the lay reader. Doubtless, also, there are some weaknesses in the author's coat of mail which the Knights of the Emmanuel movement, and of Eddyism, etc., will disclose to him when they take up the weapons of defence.

Genetic Psychology. An Introduction to an Objective and Genetic View of Intelligence. By Edwin A. Kirkpatrick, B.S., M.Ph., Author of "Fundamentals of Child Study." New York: The MacMillan Company, 1909.

Both the special student of psychology and the general reader fond of studying animal behavior will find this book of absorbing interest. It is based on the theory that "simpler forms of minds have developed into more complex forms, and the simpler feelings and ideas into those of a higher type." The beginnings and growth of consciousness from the lowest species of animal to the highest races of man are here studied, not so much with a view simply to compare and grade the intelligence of different species and races, as to ascertain thereby "what changes have taken place in the evolution of mind in the race, the order of such evolution, and the relation to each other of different types of mental activity." It is a new science. Genetic psychology begins with structure and behavior. It finds in the various organisms certain characteristics that are common to all; they are composed of protoplasm, they possess activity, and they have conscious states. The third common characteristic of all organisms, however, viz., conscious states, can only be inferred in animals from structure and behavior, "when their behavior has the same characteristics as behavior in ourselves that is accompanied by consciousness." Space does not permit of a general analysis of the book. The above gives some idea of its scope. Mental development in individuals is not discussed extensively but is left, the author states, for a subsequent volume.

Physiology and Pathology of the Urine. With Methods for Its Examination. By J. Dixon Mann, M.D., F.R.C.P., Physician to the Salford Royal Hospital; Professor of Forensic Medicine in the University of Manchester. With illustrations. Second edition, revised and enlarged. London: Charles Griffin & Co., Limited, 1908.

When the first edition of this work appeared, about five years ago, it was at once recognized as one of the very best books on the urine. At the same time it was found to differ from practically all of its competitors in that, while giving all necessary descriptions for ordinary clinical methods of investigation, it also supplemented these with details of the more elaborate processes required for research investigations. The present revision has been most thorough, much of the book having been rewritten in the light of modern advances in biological chemistry. Concise accounts are given of the most recent investigations in metabolism (so far as it affects the urine), and ample references are added, so that the reader may consult the original papers. Many new and important methods are described, and several substances which are only occasionally present in the urine are dealt with in this edition. This volume is, so far as we know, the most thorough and advanced treatise on the urine, and is confidently recommended to all who desire something more than a mere guide to uranalysis or a help to diagnosis.

Mental Medicine. Some Practical Suggestions from a Spiritual Standpoint. Five Conferences with Students at the Johns Hopkins Medical School. By Oliver Huckel, S.T.D.; Graduate University of Pennsylvania; Student at Oxford and Berlin Universities; Pastor Associate Congregational Church, Baltimore. With an Introduction by Lewellys F. Barker, M.D., Professor of Medicine in Johns Hopkins University. New York: Thomas Y. Crowell & Co., publishers.

This little volume, written by a clergyman, offers a safe and sane exposition of the ground on which the minister and the physician may cooperate in caring for the sick and afflicted, while at the same time it aims to elucidate many of the methods of self-treatment, independent of all "passing movements," along those lines of mental hygiene and spiritual control which experience has proved efficacious and which seem most likely to be of permanent value. The new cooperation of church and medicine really began with the physicians, the author states, and he says, further, that "the largest responsibility and development of the work must be in the physician's hands, the minister's part, when required, being merely cooperative, but nevertheless important." Psychotherapy he considers a new adjunct in practical theology, but its general practice in connection with religious institutions he condemns. The extravagancies and inconsistencies of Christian Science are avoided, yet cheerfulness, optimism, "don't worry," and calmness are constantly preached. The general topics of the five conferences mentioned in the title are as follows: "Mental and spiritual factors in the problems of health"; "The therapeutic value of faith and prayer"; "Possibilities in the control of subconsciousness"; "Some elements in morbid moods," and "The higher factors in the reeducation of the nerves." These conferences were really lectures to medical students, under the auspices of the Y. M. C. A., but they are presented in a clear and popular style, and apparently bear medical indorsement.

Aseptic Surgery. By Charles Barrett Lockwood, F.R.C.S.: Surgeon to St. Bartholomew's Hospital. Third Edition. London: Henry Frowde and Hodder & Stoughton, 1909.

This is not a text-book on surgery, but it will form a very valuable companion to any work on the subject. It contains notes of the author's demonstrations in the wards and operating theatre. They were originally intended to help the house surgeons, dressers, and nurses in getting ready the instruments, dressings, and materials, themselves and the patients, and also to help in attaining an aseptic environment. The methods are dealt with as simply and briefly as possible; at the same time the author makes very clear the reasons upon which the various details are based. Those who are acquainted with the author's other works will know what to expect in this, and those who are not so acquainted will find this volume a suitable introduction to writings which are at once authoritative and interesting.

Society Reports

AMERICAN ASSOCIATION OF OBSTETRICIANS AND GYNECOLOGISTS.

Twenty-second Annual Meeting, Held at Fort Wayne, Ind., September 21, 22, and 23, 1909.

The President, Dr. William Henry Humiston of Cleveland, Ohio, in the Chair.

After an address of welcome by Dr. H. A. Bruggemann, president of the Fort Wayne Medical Society, which was responded to by Dr. James Edgar Sadlier, Poughkeepsie, N. Y., the reading of papers was begun.

Advantage of the Combined Intra- and Extraperitoneal Ureterolithotomy for the Removal of Stones from the Lower Ureter.—Dr. Ernst Jonas of St. Louis said the proper operation for the removal of stones from the lower ureter (brim of the pelvis down to the bladder) must not only offer the simplest technique for the removal of the stones, but must permit an examination into possible etiological factors. The above condition might produce ureteritis, periureteritis, or increase the normal bend of the ureter to such a degree that it became kinked. As a result, small kidney stones might be arrested or increased in size in the ureter or a stone might be primarily formed in the ureter and remain there *in situ*. The only operation which enabled us to remove these causes for ureteral stone, and thus prevent recurrence of the stone, was the combined intra- and extraperitoneal ureterolithotomy.

Dr. John Young Brown of St. Louis said he had frequently been impressed with the fact that the appendix might be removed when macroscopically there was no indication that it was at fault. He did not know of any condition that was more difficult to differentiate than certain forms of chronic appendicitis and stones in the ureter. In the last year he had had nine cases in which the differential diagnosis was exceedingly difficult. In one case he found a shadow of a supposed stone in the ureter, but which proved to be a concretion in the appendix. He had another case sent to him with a diagnosis of appendicitis. He found blood in his urine. He skiagraphed the patient, and found a shadow which seemed to indicate a stone in the ureter. He did the combined operation, and not only removed a stone from the ureter, but found the appendix adherent to the right ureter, and he was inclined to believe that the condition around the appendix had a good deal to do with the development of the stone in the ureter.

Dr. Alexander Hugh Ferguson of Chicago said that the procedure varied with the side of the body. If the colicky attacks were on the right side, we should think of the appendix, and there was an indication for opening the abdomen. If the attacks were on the left side, and the patient was a man, there was no indication for opening the abdomen to remove such a stone, because it could be done more safely without the complication of an additional cut in the peritoneum. In women these stones could be reached through the bladder, when they were low down, depending upon their size, etc.

Dr. H. W. Longyear of Detroit wanted to say a word with reference to the differential diagnosis between ureteral pain and pain in the appendix. He had seen many operations on the appendix that were not justified and were prompted by the pain in the ureter under a mistaken diagnosis. In these cases there were storms of uric acid coming from intestinal toxemia. Large quantities of uric acid were thrown out from the kidney, passed down the ureter, causing inflammation of the ureter and pain, and when on the right side it was apt to be mistaken for appendicitis, and the temperature arising from the toxemia simulated appendicitis still more. These cases should be examined very carefully, so that this mistake might be avoided.

Dr. Miles F. Porter of Fort Wayne recalled a recent case in which there was typical ureteral colic and anuria. The patient had had for years a clear case of Bright's disease. In this case, as the subsequent post-mortem revealed, there was no calculous formation whatever. Moreover, the case illustrated the value of the skiagraph. The skiagram showed no ureteral calculus.

Dr. C. C. Frederick of Buffalo said there was no question but what there were many cases of pain in the right ureter for which the appendix in the past had been blamed and removed. He had seen a number of cases of this kind in his own practice, as well as in that of others, and he had been forced during the last three or four years to a realization of the fact that pain upon the right side on pressure deep down over McBurney's point did not always mean that a patient had chronic appendicitis, and he believed in many instances the trouble was in the ureter.

Dr. M. I. Rosenthal of Fort Wayne said that some four or five years ago he read a paper in which he reported a case of ureteral stone, complicating appendicitis. This was the only case he had then seen of ureteral calculus complicating appendicitis. Since then he had been careful to investigate the right ureter in operations for appendicitis, and he had not met with another such case. This would indicate that this complication was not frequent, although it did occur.

Dr. Hugo O. Pantzer of Indianapolis stated that in operating on a case of gangrenous cholecystitis, with a discharge of the contents of the gall-bladder into the peritoneal cavity, he was led to examine lower down, and found at the bifurcation of the abdominal aorta a number of stones which were hard and fixed to the feel. He removed one of these stones and found it to be a calcareous degeneration of tuberculous glands. The history of the case would seem to show that this woman, fifty years of age, had in early life a tuberculosis appertaining to this lower part.

Dr. John W. Keefe of Providence said that in one case he introduced a wax-tipped catheter and found markings on the wax. The catheter was introduced in the pelvis of the kidney, and on the day the patient was to be operated on he again passed the wax-tipped catheter to the kidney, made his incision in the loin, and found the catheter in contact with the stone in the kidney, showing that the first markings on the wax were correct.

Dr. K. I. Sanes of Pittsburg cited a case illustrating the difficulty of making a differential diagnosis between ureteral trouble and appendicitis, saying that this difficulty was not only met with in chronic, but in the acute cases of appendicitis.

The Surgical Treatment of Tumors of the Bladder.—Dr. John W. Keefe of Providence, R. I., said that the surgery of tumors of the urinary bladder was in a transitional state. The last word had not been said. While the perineal and vaginal routes had been abandoned by most surgeons, some now preferred the urethral, while others the suprapubic (extraperitoneal), and yet others the abdominal intraperitoneal route, or a combination of both. The medical treatment of tumors of the bladder was often prolonged until surgery was of no avail. The suprapubic operation was the method most frequently employed at the present time, although the abdominal intraperitoneal route had many points in its favor. It gave one plenty of room in which to operate, and one could see exactly where to excise or cauterize the growth. The author summed up as follows: "1. Cystoscopic examination to determine the site and character of the tumor. 2. Ureteral catheterization. The catheter is left in the ureter as a guide during the operation. 3. The high Trendelenburg position. 4. Opening the abdominal cavity to locate the growth accurately, to aid in separating the peritoneum from the bladder over the site of the tumor,

and also to allow plenty of space in which to operate. 5. An assistant locates the growth in the bladder with a cystoscope during the operation. 6. Closure of the peritoneal cavity, the growth now being removed through an extraperitoneal wound. 7. Immediate suture of the bladder. 8. The patient voids urine or is catheterized at frequent intervals."

Dr. C. C. Frederick of Buffalo had operated upon three cases for malignant disease of the bladder. In the first case the tumor was located in the posterior wall of the bladder, in a woman, just back of the trigone. Following the removal of the tumor she made a good recovery, went on for two or three years, and he supposed was going to get perfectly well. But she had a recurrence to the left side of the original scar. She did not have a secondary operation, and eventually died of anemia.

Dr. Ernst Jonas of St. Louis said that with the cystoscope we were usually able to settle definitely the size of the tumor, but not its character.

Dr. M. I. Rosenthal of Fort Wayne related a case of cancer of the uterus which involved the bladder. In this case he did a radical operation for the removal of the uterine cancer, also removing a piece of the bladder in a woman fifty-eight years of age. She was still in fairly good health.

Operative Enlargement of the Pelvis of the Non-Pregnant Woman.—Dr. John N. Bell of Detroit stated that the operation of pubiotomy as a means of effecting delivery in moderately contracted pelves, where a trial at labor had taken place and efforts to deliver with the forceps had failed, was now an established operation. The writer did not wish to be placed in the position of advocating this procedure in preference to premature delivery at the eighth month, or primary cesarean section at term, but for discussion assumed that the operation was a justifiable one, and to that end presented arguments tending to such a conclusion.

Dr. E. Gustav Zinke of Cincinnati said he could not see what we could possibly gain by attempting to enlarge the pelvic ring in the non-pregnant state in the hope of facilitating labor at the end of term. The skiagraph presented by the author showed very little space gained in the line of separation of the bone by the pubiotomy that was performed. From what he had learned in listening to this paper he had received no inducement to adopt the procedure mentioned in the paper.

Dr. Albert Goldspohn of Chicago pointed out that the chief objection to this procedure was that when such a separation in the pelvic ring was made at the time of childbirth a very much greater separation of this bone occurred during the transit of the child, a separation of two inches occurring in extreme cases.

Dr. Ralph Waldo Lobenstine of New York could not see any possible advantage in doing this operation, with all due respect to the author. With the test of labor in a pelvis that would allow a baby to go through, with only a gain of one centimeter by pubiotomy, the baby would pass through without such an operation. In this particular type of pelvis, justominor pelvis, the most surprising results occurred without any operation, where we had an external conjugate of seventeen centimeters and the other measurements corresponded, because we got marked flexion of the child's head, whether we were dealing with an exterior or posterior position, this flexion permitting the head to be driven out through the justominor pelvis.

Chylous Cyst of Iliac Mesentery.—Dr. Charles E. Congdon of Buffalo reported a case in a boy six years old, on whom he operated, making the usual incision as for an appendix operation. On opening the abdomen a tense cystic tumor presented. The tumor resembled an ovarian cyst, but was more elastic, and it had the color of omentum. On enlarging the abdominal incision, the tumor was found to be the distended iliac mesentery, beginning about eighteen inches above the ileocecal valve. It was ovoid, with a valley lodging the bowel, and dwindling toward the posterior mesenteric attachment into a wedge-shaped separation of the mesenteric layers. The ileum corresponding to the mesenteric cyst was compressed into a white cord, while above it was distended. After incising the cyst about two quarts of milky fluid gradually drained away, there was a reduction of tension, allowing the vessels of the bowels to fill and the pallor disappear, while the relief of pressure caused the lumen of the bowel to become patulous, and the distention above passed away. The cyst was sutured to the abdominal incision, and was drained by a rubber tube held in place by a stitch, otherwise the abdominal incision was closed with through-and-through sutures of silkworm gut. Relief was almost immediate.

Dr. Miles F. Porter of Fort Wayne related a case in which, upon opening the abdomen, he found he had a volvulus to deal with, but in unraveling the volvulus he found it was due to what proved to be chylous cysts of the mesentery. He made a resection of the gut, but the patient died from the continued progress of the peritoneal infection.

Dr. Ernst Jonas said, in regard to intestinal obstruction produced by chylous cyst, he wished to emphasize the importance of not giving medicines with a view to relieving such intestinal obstruction when it was caused by the cysts. We should never try at this stage in surgery to remedy ileus by medicines given by mouth, as it was impossible to accomplish anything by them in any case of true obstruction.

Dr. Alexander Hugh Ferguson had never encountered a case of chylous cyst of the mesentery in his surgical experience, and he thought it was well in discussing such papers to point out the relative infrequency of these cases.

President's Address.—President Humiston discussed the Gilliam operation for retrodisplacement of the uterus, saying he had employed it in a large number of cases, with gratifying results.

Dr. Hugo O. Pantzer of Indianapolis read a paper in which he discussed some phases of puerperal sepsis, and reported a number of cases.

The Embryo Abdominal Surgeon with Inadequate Preparation and Knowledge.—Dr. J. Henry Carstens of Detroit said that in every large center, say the county seat, there ought to be a hospital and a surgeon, or surgeons, who have been prepared by a thorough course of hospital training, and they should limit their practice to surgery, and not compete with their colleagues. State boards should take up this question and issue a special license to those who wanted to practise special lines of surgery. In conclusion, he would say: "1. Abdominal surgery by embryo surgeons should be prohibited. 2. Thorough preparation in a proper hospital as an assistant for one year should be the minimum requirement. 3. Those who want to practise abdominal surgery should furnish evidence of qualification. 4. Nothing herein contained should prevent any general practitioner from doing abdominal surgery in an emergency."

When Shall We Operate for Ruptured Ectopic Gestation?—Dr. R. R. Huggins of Pittsburg said it was his habit to delay operation for a few hours in ruptured tubal pregnancy when all signs pointed toward a temporary cessation of the hemorrhage. In the vast majority of instances the hemorrhage had ceased temporarily when the consultant was called. The length of time which had transpired since the hemorrhage began varied. The attending physician would usually say that when he first saw the patient she was in a state of collapse, but that now, which was several hours later, there was some improvement. The pulse was slightly better, the air hunger

had disappeared, etc. A pulse, which was hardly perceptible when he first saw the patient, was now easily counted, and was of better volume. Reaction had already begun. The formation of a clot in the pelvis had plugged the bleeding point and the force of the blood stream was now so low that for a time, at least, there was little danger of recurring hemorrhage. Who could say, and by what means were we to determine, how long this period of apparent rescue from death by nature's efforts might continue? We all knew, owing to the increased blood supply to the pelvic organs during pregnancy, how profusely a small wound made in the uterus, or, in fact, in any part of the pelvis, would bleed. Without careful consideration of the above demonstrated facts, experiments upon animals in the study of this subject were of no practical importance. It was irrelevant to compare hemorrhage from other parts of the body to that which occurred from the torn vessels of a congested pregnant tube. In five or six per cent. of the cases of ruptured tubal pregnancies the hemorrhage was tremendous, and the symptoms correspondingly grave. The patient was pulseless and usually restless, with the anxious look so characteristic of extreme hemorrhage. The blanched mucous membranes and deathly pallor indicated the gravity of the condition and at once suggested the diagnosis. Recent papers advocating delay in operation had served an important purpose, because they had emphasized the fact that the patient usually rallied from the primary hemorrhage, and that it was unnecessary as a rule to operate while the patient was in extreme shock. It was undoubtedly true that in a large percentage of the cases a few hours could be well spent in allowing the patient to react so that operation would be attended by less danger. That it could be postponed indefinitely without great risk to the patient had not been true in the speaker's experience. It was unnecessary to dwell on the dangers of peritonitis, intestinal obstruction, and prolonged convalescence, which would result occasionally if operation was indefinitely postponed.

Dr. H. W. Longyear of Detroit said there should be no hesitation on the part of the surgeon in regard to the necessity of operating immediately in cases of recent ruptured tubal pregnancy.

Dr. Hugo O. Pantzer of Indianapolis stated that standing, as we did in this class of cases, oftentimes in the presence of doubt, where life was menaced, we could not decide otherwise than to chance it, with the doubt in favor of an operation.

Dr. Wm. H. Humiston of Cleveland said that this was an important paper, especially after the information had been given out from other sources that in a large majority of cases we could delay operation, and that perhaps an operation might not be necessary. Delay was dangerous. There should be very little trouble in making a diagnosis of ruptured ectopic pregnancy. If the rupture was sufficient to cause shock, one could not tell whether the shock would be overcome or not, and he did not hesitate to operate upon all of these cases that came into his hands, whether the patients were in shock or not.

Dr. Thomas B. Noble of Indianapolis thought it was bad teaching to advise delay in operating on cases of ruptured ectopic pregnancy. When Dr. Robb advocated procrastination, he said that some women would die as the result of such teaching. He subscribed *in toto* to the advice given by the author of the paper, and affirmed that these cases should be operated on immediately.

Dr. A. B. Miller of Syracuse, N. Y., said we should not procrastinate in operating upon these cases of ruptured ectopic pregnancy promptly. In over a hundred cases operated on immediately, he had lost only three.

Dr. John Young Brown of St. Louis had seen quite a number of cases of ectopic pregnancy, and he had not been able to figure out from this experience why gynecologists should differ as to the proper time to operate on these cases. With our modern methods of combating shock, and particularly by the use of salt solution by hypodermoclysis and by the method which Andrews had accentuated in the treatment of gunshot wounds, where the hemorrhage was severe, viz., buttonholing the upper abdomen as soon as it was opened, and starting the salt solution to flow immediately upon the opening of the abdomen to combat shock, if not for irrigation, a large majority of these patients could be saved by prompt action.

Dr. Albert Goldspohn of Chicago said that of something like eighty cases of ectopic pregnancy he had dealt with in one way or another he had only known of two patients to die from this affection who were not operated on.

Dr. C. C. Frederick of Buffalo had operated on about 130 or 140 cases of ectopic pregnancy in his city. Five per cent. of these had been rapidly bleeding cases, and the other 95 per cent. were cases in which rupture had taken place, and there were symptoms of recurrent bleeding extended over a period of two, three, four, or five weeks, or even six months. He had operated on women who had recurrent hemorrhages five or six months after the primary rupture. He recalled one case in which hemorrhage stopped; the woman did not have another rupture, and she was not operated on. All things considered, he was in favor of early operation in cases of ruptured ectopic pregnancy. He believed we should insist on stopping hemorrhage in these cases, as well as bleeding, which might take place in any other part of the body, namely, by tying the bleeding vessel and stopping the hemorrhage.

Dr. M. I. Rosenthal of Fort Wayne said it had been his practice to operate on these cases of ruptured ectopic pregnancy as soon as the diagnosis was made. In all of the cases that he diagnosed early and operated on, there had been no deaths, but in those that were operated on late he got a mortality in each case.

Dr. E. Gustave Zinke said it was just as wrong to say that every case of ectopic gestation must be operated on as it was that every case of this nature did not need operation. There were patients who recovered without operation. This should not be forgotten. The members probably knew of instances where operation had been proposed, with counsel and without counsel, was refused by the family, and patients had recovered, and they had the laugh on the operators. He agree dwith Dr. Robb, and said he must protest against operating in every case of ruptured ectopic pregnancy.

Dr. J. Henry Carstens of Detroit said if a woman was suffering from an internal hemorrhage, as that from a ruptured ectopic pregnancy, she ought to be operated upon promptly. He believed in operating on these cases promptly and arresting the hemorrhage. If he did not do it, he said, he could not sleep very well.

Dr. John Young Brown of St. Louis described a case in which there was an artificial anus following an operation for intussusception. In this case there was complete occlusion of the large bowel for three years. He described the method of restoring its continuity.

Rupture of the Uterus.—Dr. Ralph Waldo Lobenstine of New York presented a study based on seventy-eight cases treated at the New York Lying-in Hospital. He said that ruptures of the uterus during labor might be divided into complete and incomplete ruptures of the vaginal vault. Of the 78 cases in the series, there were 46 complete ruptures, 29 incomplete, and 3 ruptures of the vaginal vault. The common location for the rupture was the lower uterine zone. There were two fundamental types, the longitudinal and the transverse, but there was often more or less fusion of these types. In the list there were 26 that probably started as the vertical type,

and 20 as the transverse. Of the 26 longitudinal tears, 18 occurred on the left side, 6 on the right, and 2 near the midline. Of the 20 transverse ruptures, 13 occurred on the anterior wall and 7 on the posterior. Of the 46 cases treated in the hospital, there were 3 cases of rupture at the uterovaginal junction in these series. Such ruptures were seen most frequently as the result of transverse presentation and of trauma due to faulty instrumentation. The posterior vaginal vault was injured more frequently than the anterior. The spontaneous ruptures were due to a tremendous distention and stretching of either anterior or posterior vaginal vault. The pelvic contraction was usually of high grade.

Calcareous Degeneration of the Fibroad Uterus.—Dr. Walter B. Dorsett of St. Louis read a paper on this subject and presented the specimen. On the opening of the abdomen the tumor was found lying loosely in the pelvis and unattached. On grasping the mass the operator was reminded of the sensation usually imparted in the handling of uterine fibroids with a long pedicle. A supravaginal amputation was done, and the abdomen closed within a few minutes. The patient made an uninterrupted recovery, and left the hospital within eighteen days, well, and relieved of her distressing symptoms. The ligation of the renal artery of the rabbit by Litten, and his subsequent discovery of deposition of calcium salts in the renal tubules, probably proved that the true etiology of calcareous deposits lay in a retrograde process, due to deficiency of the blood supply. It could readily be seen that during the normal atrophic changes in the uterus, due to decreased determination of blood toward the uterus, degenerative changes were apt to occur.

Dr. J. Henry Carstens said that some thirty or more years ago a woman came to the dispensary with fibroid tumors. At that time they did not operate on these tumors so frequently as they did to-day. She was not operated on then. About five years ago she presented herself with three tumors which were jammed in the pelvis, causing obstruction of the bowels and bladder. He operated on her, removing one tumor about six inches long and four inches in diameter. These tumors were so hard that he could not cut them open, but had to split them with a hatchet to show the calcareous deposits. No matter how long these cases were allowed to go, these tumors either underwent calcareous degeneration or became malignant, so on general principles all fibroid tumors ought to be removed.

Dr. Hugo O. Pantzer reported a case which was similar in every respect to the one related by the author of the paper.

Ovarian Pregnancy at Term.—Dr. Walter C. G. Kirchner of St. Louis reported a case of extra uterine pregnancy at term. The clinical symptoms were those associated with tubal pregnancy. At a later stage the patient had the usual symptoms attending uterine pregnancy at term. The tumor mass originated in the right ovarian region, and as pregnancy advanced the tumor was pushed toward the left side. The patient felt fetal movements about the fifth month of pregnancy. The condition was complicated by prolapse of the uterus with pronounced edema of the cervix. The patient was submitted to operation, and on doing a laparotomy a cyst-like tumor was delivered through the abdominal opening. The mass resembled an ovarian cyst, and contained the fetus. This was found to be full term and well developed. It was easily resuscitated, and it was in good health. The tumor mass was complicated by omental and intestinal adhesions. The appendix was adherent and appendectomy was performed. The left tube was free. The right tube was incorporated with the outer surface of the gestation sac. Ovarian ligament was connected with the gestation sac. The sac originated in the right ovarian region, where a broad pedicle had formed, which was ligated and severed. In this region also the main blood supply was obtained. The gestation sac contained the placenta and fetal membrane. The placenta was not associated with either tube, and was free in the abdominal cavity. It occupied a central and anterior position in the gestation sac. The diagnosis, ovarian pregnancy, was based on the presence of the uteroovarian ligament, the normal condition of both tubes, the location of the tumors, and the microscopical evidence of the examination of the gestation sac.

Dr. E. Gustav Zinke said ovarian pregnancy was a very rare thing, and he was glad they brought before them a case which left no doubt in their minds as to its real character. It was remarkable what nature would not do under these circumstances, when the ovum was implanted ectopically. The most frequent cases of ectopic gestation which go to full term were those where the tube held out to the last. It was comparatively rare, it was true, but these were the cases in which there were no adhesions between the abdominal viscera and the ectopic gestation sac. The next in frequency was the ovarian, but here very often rupture took place because of the brittle character of the ovarian tissue. There was another variety of ectopic gestation which went to term, but which was the rarest of them all, and that was in cases of tubal rupture, or in tuboovarian pregnancy rupture took place sufficiently to permit the amniotic sac, with the decidua reflexa, which was formed under these circumstances, to escape into the abdominal cavity. Here the placenta continued to grow within the tube and ovary, as the case might be. Sometimes it made its way outside of the structures and implanted itself on the pelvic wall. Occasionally it happened that the membranes were broken because of the movement of the fetus, and then the fetus was found free in the abdominal cavity.

Dr. Ernst Jonas said he recalled a case operated on by Dr. Tuholske when he was assisting him, where in the second month of pregnancy the entire ovum was swept away from its seat of implanation in the right tube into the free abdominal cavity, implanted itself in the region of the liver, changed the liver tissue, the peritoneum covering the kidney, and parietal peritoneum to such a degree that it was able to change these tissues to true decidual tissue. The pregnancy went on to term and the child was removed at the end of pregnancy alive. The month died twelve hours after the operation. He did not know at the time why she died. The specimen which he had in his possession showed it would have been impossible to have removed the placenta by force from these organs.

Dr. A. B. Miller said that a specimen of an ovary which contained an ovum perhaps of two months' development had been recently placed in the pathological museum of his college at Syracuse. The case was operated on by a neighboring surgeon, he supposing he was simply dealing with an ovarian cyst. The patient came to him complaining of more or less pain, and on examination there was a small globular mass found in the pelvis. Without taking the history of the patient as to the possibility of this being a pregnancy the woman was operated on, the ovary removed and found to contain this small embryo.

A Study of Four Hundred and Forty Operations on the Appendix, with Remarks.—Dr. Edward J. Ill of Newark, N. J., deplored the late diagnosis and the too frequent use of the hypodermic syringe; but for these the general results would be much better. Among the 440 operations 40 per cent. were males, 60 per cent. females. In 81 women the appendix was removed incidentally, while other surgical conditions prevailed and many were shown to be normal by the pathologist. He deplored the frequency with which the appendix was removed simply because the abdomen was opened, and believed that no operation should be done except for the express purpose

of removing symptoms of disease for which the patient sought our advice. Any prolongation of the operation might add to the patient's danger and certainly to his discomfort during convalescence. The youngest person operated on was five years old and the oldest one was sixty-five years old. Forty-three per cent. were suppurating cases. Among the 189 septic cases there was a localized abscess in 109; there was diffuse suppurative peritonitis in 70; what seemed to be a general peritonitis was recorded in 8 cases; and 2 cases had septicemia. The total number of deaths was 32, or 7.2 per cent. Increased experience showed a marked reduction in the death rate. Thus in the first 100 it was 18 per cent.; in the second 100 it was 6 per cent.; in the third 100 it was 5 per cent., and in the fourth 100 it was 3 per cent. The total number of deaths in the non-suppurating cases was 2, or 0.8 per cent. The percentage of deaths in the suppurating cases was 14.3 per cent. Late and hopeless cases accounted for this high death rate. An interesting fact in the death rate was the personal one in the after treatment. Thus in 198 cases that were looked after personally by the writer, the death rate was 3.6 per cent., while in 185 cases looked after by the attending physician the death rate was 10.3 per cent., or nearly three times as great. The death rate of the diffuse suppurative peritonitis was 10 per cent. The writer had collected from various hospital reports throughout the country 7,833 operations for appendicitis. The death rate from the non-suppurating cases was 3.7 per cent., while the suppurating cases showed a death rate of 26 per cent. The author was never obliged to reopen the abdomen for late symptoms or adhesions. He advised removal of the appendix in all cases if it could be done in a reasonable time, depending on the condition of the patient. He urged the use of absorbable suture material in all septic cases. He had used most of the techniques recommended for the removal of the appendix, but had always returned to the cautery above the ligature and the purse-string suture. He insisted that much mischief had been done by not draining septic cases. In these cases he had adopted the right lateral semiprone posture in such a way that the opening in the abdomen was in the most dependent part of the peritoneal cavity. The drain could thus be brought out through the upper end of the incision, thus reducing to a minimum the danger of hernia, of which he had seen less than 1 per cent. in his cases, and this also did away with the stab incision in the loin. The position was kept up for twenty-four hours.

A New Point in Diagnosis Between Appendicitis and Tubal Diseases.—Dr. Robert T. Morris of New York said that hypersensitiveness at the site of the right group of lumbar ganglia indicated that the appendix alone was the center of irritation. Hypersensitiveness of both right and left groups of lumbar ganglia indicated that some pelvic structure was the center of irritation. In cases in which there was a question if the appendix or some pelvic structure was causing local or reflex disturbance, they could commonly make a differential diagnosis at once by making deep pressure over the sites of both groups of lumbar ganglia and noting whether these groups or only the right group were sensitive to an important degree.

Is the Routine Exhibition of the Preoperative Purge Defensible?—Dr. Edwin Walker of Evansville, Ind., read a paper on this subject in which he drew the following conclusions: Purgatives could do harm and should be given only when indications were clear. The profession should abandon the slipshod, routine methods now in vogue and should teach the laity, both by precept and example, the evils of the purgative habit. The practice of purging all patients before surgical operations was unnecessary and injurious; they were made more uncomfortable, were weakened, and the condition of the intestinal canal was not rendered more favorable, but, on the contrary, germ activity was stimulated, just as it was in enteritis, increasing the probability of infection when the gut was opened and there was, in addition to this, more postoperative tympany. A diet of digestible food for twenty-four hours or more and a fast of eight or twelve hours before would put the intestine in the best possible condition for any operation, especially on the intestinal canal, except where obstructive lesions existed, and for these purgatives were worse than useless and other measures were required. In a few cases of milder fecal stasis a purgative several days before operation followed by enemas was of service. These were, however, extremely rare. The routine use of any powerful drug was to be deplored and the habitual preoperative purge was indefensible. The continuance of this practice indicated stasis of the surgical mind.

Cesarean Section, Abdominal and Vaginal, Compared and Contrasted.—Dr. Miles F. Porter of Fort Wayne said: (1) With a living and viable child the abdominal is the operation of choice; (2) the vaginal operation is probably never indicated in placenta previa; (3) in cases demanding quick delivery where the only obstacle is an undilated os, the vaginal operation should be done; (4) infection should not decide us in favor of either operation, but the fact that its existence adds to the mortality of both should admonish us that neither is to be regarded as an operation of *dernier ressort*; (5) with a dead or dying mother and a living, viable child, the abdominal operation should be done; (6) better knowledge of the indications for these operations and a timely resort to them would materially reduce both the maternal and fetal mortality and morbidity.

Methods of Drainage in Abdominal and Pelvic Surgery.—Dr. James F. Baldwin of Columbus, O., said that in this paper he urged the more frequent resort to vaginal drainage in pelvic cases in which pus was present or extensive adhesions and drainage through a stab incision in certain cases of appendicitis. He advised the use of gauze not so much for real drainage as to keep the intestines from contact with raw or infected surfaces. He deprecated the use of the word drainage in these cases and suggested that the word "fluffage" would be more appropriate for the purposes intended. The gauze was passed through an incision in the vaginal vault from above down, the opening in the vault being of ample size, and the gauze being then so placed as to lightly fill the pelvis. In this way the gauze kept the intestines out of the pelvis and at the same time absorbed all discharges. The gauze was left in place one week and then withdrawn. Sterile douches were then used until the cavity thus left became obliterated. He had used this method for many years and in a large number of cases with entirely satisfactory results, both immediate and remote.

How Can We Best Educate Our Women to Seek Relief Early from Carcinoma of the Uterus?—Dr. C. C. Frederick of Buffalo said that the statistics of operations both should admonish us that neither is to be regarded as German clinics than in this country, not because they had more skillful operators, but because the women were operated upon earlier, their women having been taught to consult the surgeon earlier when they had symptoms of malignant disease of the uterus. He thought there was a belief among general practitioners in this country that hysterectomy for carcinoma of the uterus was an unsuccessful operation, in so far as it prevented recurrence. Such had been the case and would continue to be so long as women so suffering were not operated upon earlier than they had been in the past. Early radical operations gave good results, and they ought progressively to give better and better results. Hysterectomy for carcinoma of the body of the uterus gave notably better results even in late cases than when the cervix was involved. Our women

should not only be taught that early operation gave better results, but also that the severity of the operation and the mortality and the morbidity were decreased thereby.

Phlegmasia Alba Dolens.—Dr. William A. B. Sellman of Baltimore reported a case of this nature in connection with an ovarian tumor. He presented photographs showing the size of the tumor, the amount of abdominal distention, and the swollen limb. He considered the phlegmasia dolens in this case was due to pressure upon the iliac vessels on the left side, and that this pressure was immediately relieved with removal of the tumor. The patient was fortunate in the rapid restoration of the circulation and in not having had a clot form, which might have destroyed her life by the entire clot or a portion passing to the heart.

Removal of Upper Portion of Rectum and Sigmoid.—Dr. Thomas B. Noble of Indianapolis related the case of a married woman, thirty-three years of age, in whom he extirpated the upper portion of the rectum and sigmoid for cancer. In connection with this case he showed an instrument which he thought would be helpful in this class of cases. It was the result of a study and use of Murphy's button. It had some advantages over the button in this class of work, in that it could be introduced more quickly; it served as a splint to the soft parts; admitted of irrigation of the colon, and the prevention of impaction, and by continuous drainage kept the bowel quiet, thereby favoring prompt and perfect union. He believed it was a useful means to the ideal end, namely, an intact abdomen, intact intestine, and competent anal sphincters.

Malignant Tumor of Undescended Testicle.—Dr. O. G. Pfaff of Indianapolis said that the patient was a man, thirty-eight years of age. Examination disclosed a tumor the size of a fetal head, occupying the left lower abdomen and pelvis. The tumor was freely movable within moderate limits, but was apparently attached by a pedicle to a point near the internal inguinal ring. The mass was considered to be a malignant tumor of the undescended left testicle, and three days later the man submitted to operation. Through an incision made to the left of the median line the relationships of the mass were easily made out. The pedicle was attached to the internal ring, and there were some recent adhesions to the bladder, which were broken up easily, the pedicle ligated, and the mass removed. The man made an uneventful recovery from the operation, but within five months died of malignant disease. He did not see him after he left the hospital, and did not learn as to the location of the later growth other than that it seemed to affect both the bladder and the bowels. The microscopical examination of the growth showed it to be a large round celled sarcoma.

Terminal Events in Gallstone Disease.—Dr. Charles N. Smith of Toledo, O., said that gallstone disease was very prevalent, afflicting from 7 to 10 per cent. of adults dying in the public hospitals of England, Germany, and America, was a contention apparently substantiated by the records of thousands of post-mortem examinations. Rupture of the suppurating gall-bladder into the general peritoneal cavity was by no means an unusual terminal event, having occurred five times in his own experience. Of these five cases four made a complete recovery after operation, while the remaining one, a desperate and delayed case, with a widespread peritonitis, died on the table as the abdominal incision was completed. From observation of these and other cases and from a study of the literature of the subject, he was convinced that the frequency with which rupture of the gall-bladder occurred as a terminal event in gallstone disease was scarcely appreciated. These cases were commonly diagnosed as peritoneal infection from appendicitis, operated on as such, and so recorded unless gallstones, correcting the diagnosis, were found in the peritoneal cavity. Of the many terminal events of gallstone disease, malignancy was without question the most hopeless from the standpoint of cure. That primary malignant disease of the gall-bladder and duct was preceded by gallstones in practically every instance was the experience of surgeons and pathologists. It would seem that a due appreciation of the frequent occurrence and the serious import of these complications must lead to the surgical removal of gallstones as a conservative and prophylactic measure long before the opportunity was given for the onset of these terminal events. That this might be done would require a more general recognition of the initial symptoms of gallstone disease, with diagnosis based thereon, rather than upon the symptoms produced by these same terminal events.

Dr. Milas F. Porter emphasized what the author had said regarding the relative frequency of the terminal events of gallstone disease and the consequent importance of operating on cases of gallstones before these more serious results occurred. He was interested in what the author said regarding posterior gastroenterostomy in those cases in which the pylorus was obstructed because of adhesions about it or the gut below; or because, on the other hand, of adhesions that were hard to break up which hung the pyloric orifice up under the liver. This had occurred a number of times, and in some of these cases the separation of the adhesions had not only been difficult, but accompanied by considerable trauma of the liver, and it was not unattended by danger. In many cases after these adhesions were liberated, one would still have the greater difficulty to overcome, namely, their reformation in the position they were before, and he was therefore impressed with the fact that in many of these cases they could be better treated by posterior gastroenterostomy, in so far as the relief of this feature was concerned.

Dr. Thomas B. Noble referred to that condition in which by pericholecystitis there were changes occurring in the stomach due to engorgement by the inflammatory exudate upon the pyloric area. In such conditions we would have gastric neuroses, as well as true anatomical disturbances following. While the author had advised gastroenterostomy in such conditions, the speaker preferred the Finney operation. He did not favor establishing an artificial opening between the intestine and stomach unless every other procedure failed. But the Finney operation maintained the normal route, made drainage free and perfect, and in the five cases in which he had practised it he had had very satisfactory results.

Dr. Howard W. Longyear of Detroit read a paper on nephrocoloptosis which was illustrated with numerous lantern slides.

Officers.—The following officers were elected for the ensuing year: *President*, Dr. A. B. Miller of Syracuse, N. Y.; *First Vice-President*, Dr. Charles N. Smith of Toledo, O.; *Second Vice-President*, Dr. Raleigh R. Huggins of Pittsburg, Pa.; *Secretary*, Dr. William Warren Potter of Buffalo, reelected; *Treasurer*, Dr. X. O. Werder of Pittsburg, Pa. Syracuse, N. Y., was selected as the place for holding the next annual meeting; time, September 20, 21, and 22, 1910.

Diphtheritic Enteritis.—R. E. McKechnie reports the case of a girl of six years of age who was taken ill at Suva, Fiji, with a mild dysentery, which lasted until she reached Vancouver. She had several stools each day containing blood, mucus, and pus. Examination of the stools excluded both ameba and the Shiga bacillus, but showed many streptococci. Streptolytic serum caused these to diminish, but the symptoms did not abate. Later cultures showed diphtheria bacilli. Diphtheria antitoxin caused immediate improvement in the symptoms, and after two days a cylindrical cast of the bowel four inches in length was passed. Recovery was uninterrupted. The cast proved to be a true diphtheria membrane. The patellar reflexes were absent, and a paralysis of the anus, lasting two weeks, developed.—*The Montreal Medical Journal.*

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

Ohio State Board of Medical Registration and Examination.

June 8, 9, and 10, 1909.

ANATOMY.

1. Enumerate the bones forming the orbit.
2. Give the nerve supply of the stomach.
3. Name the ligaments of the knee-joint.
4. Describe the lungs, briefly.
5. Describe histologically the structure of the kidney.
6. Give the arteries arising from the thoracic aorta in order, beginning at the heart.
7. Give the composition of bones and classify them.
8. Name the structures forming the larynx.
9. Describe the gastrocnemius muscle.
10. Describe the femur.

PHYSIOLOGY.

1. What are some of the properties of protoplasm?
2. Describe a neuron.
3. What is ameboid movement?
4. What are capillaries, and what function do they perform?
5. What forces contribute to the flow of blood through the veins?
6. What is reflex action?
7. In what does digestion and nutrition consist?
8. What function is performed by hydrochloric acid in digestion?
9. What is the nutritive value of proteids? Name some articles of food containing a large proportion of proteid.
10. How should cow's milk be modified to resemble human milk?

CHEMISTRY.

1. Milk: Give its composition. What impurities are most common and how would you detect them?
2. What is the chemical difference between acids having the termination ous and ic? What names are given to compounds of such acids?
3. What effect do alkalies have on gastric secretions?
4. Name and describe three general methods for the purification of water.
5. Explain where and how HCl is made in the human body.
6. How are urates formed in the system, and how would you recognize them?
7. What is a calcium sulphide? Give its properties and uses.
8. What are the common properties of the mineral acids?
9. State the toxicological effect of carbolic acid and the therapeutic measures you would employ in a case of poisoning.
10. What is meant by physiological antidotes? Name some you consider physiological for strychnine poisoning.

MATERIA MEDICA AND THERAPEUTICS.

1. Name and give the physical characteristics and properties of the official salts and preparations of mercury commonly employed.
2. Name the more important official preparations of digitalis. Under what conditions would you prescribe each?
3. Name the various serums whose place in medicine is recognized, and give uses of each. Also state modes of administration.
4. In what form should the iodides be administered? With what are they incompatible?
5. Discuss the comparative value of ether and chloroform as general anesthetics. Give contraindications for each, and treatment for untoward effects.
6. In what particular conditions would you advise suggestive therapeutics? State briefly how you would manage a case requiring this treatment.
7. What symptoms follow the continued use of cocaine? How would you treat a cocaine habitué?
8. What indications would suggest digitalis or the nitrite group in cardiovascular disease?
9. Define alkaloids, give their common characteristics and physical properties.
10. When would you use galvanism and when the faradic current?

PRACTICE OF MEDICINE.

1. Name four diseases in which a leukocyte count of over 25,000 is probably present.
2. Differentiate a large ovarian cyst from hydronephrosis of the right kidney.
3. Differential diagnosis of lead colic.
4. Name the cardinal symptoms of aortic stenosis.
5. How would you treat bronchopneumonia in a child?
6. Diagnose empyema. How treat it?
7. Differentiate gallstones and appendicitis.
8. What is paranoia?
9. How would you manage a case of pulmonary tuberculosis in an ordinary family and home, with a view to the prevention of infection to others?
10. What is the difference between active and passive hyperemia?

DIAGNOSIS.

1. State pathological significance of an excessive respiratory action of the abdomen—abdominal respiration.
2. A persistently frequent pulse in persons without fever, what affections may it suggest?
3. What pathologic significance is attached to amenorrhea?
4. What results follow a back pressure of the superior cava?
5. State physical signs of pyloric stenosis.

SURGERY.

1. Describe a compound, comminuted fracture, and give general treatment for same.
2. Where are ununited fractures most commonly found? Give some of the causes and treatment.
3. Describe ileus, and give treatment.
4. What injuries are common to the knee-joint? Give treatment for same.
5. Give diagnostic symptoms and treatment of incipient coxalgia.
6. Describe symptoms and give treatment of flat-foot.
7. Give diagnostic symptoms of tuberculous kidney.
8. Give technique of suprapubic prostatectomy.
9. Give symptoms and surgical treatment of renal calculi.
10. Describe surgical management of chronic cystitis.

OBSTETRICS.

1. What factors make up the expulsive forces of labor?
2. What group of symptoms and what signs in particular would suggest to you pregnancy in a primipara at two months' gestation?
3. Give the measurements obtained by external pelvimetry that would indicate a normal birth canal. What value can be placed upon such measurements?
4. What advantage, if any, to mother and child is gained by intermittent contractions of the uterus during labor?
5. In endeavoring, wholly by external examination, to determine the presentation and position of the fetus at about term, what anatomical guides are employed?
6. Describe the development of the bladder in embryo.
7. Make a differential diagnosis between a fibroid of the uterus and an ovarian cyst.
8. Give briefly the etiology and treatment of suppurative inflammation of a vulvovaginal gland.
9. Give the causation and general symptomatology of subinvolution of the uterus.
10. What treatment would you suggest for senile vaginitis?

DERMATOLOGY, SYPHILOLOGY, AND DISEASES OF THE EYE, EAR, NOSE, AND THROAT.

1. Describe scabies. What is the cause of the disease? How is it treated?
2. What is dermatitis? Mention its varieties.
3. Describe psoriasis.
4. Are there any general characteristics to distinguish syphiloderma from other diseases of the skin?
5. What is syphilitic gumma?
6. How do you recognize astigmatism subjectively and objectively?
7. Define glaucoma, enumerate its varieties, and mention principal symptoms.
8. Describe symptoms of catarrhal otitis media.
9. Describe mucous polypi of nasal cavities and give their causes.
10. Chronic laryngitis: Symptoms and causes.

PATHOLOGY, BACTERIOLOGY, AND HYGIENE.

1. What is the microscopical appearance of the kidney during acute congestion?
2. Name the different kinds of tissue degeneration.
3. Name four possible sequelæ which may follow peptic ulcer of the stomach.
4. Describe the microscopical appearance of a gumma.
5. What is the so-called "nutmeg" liver? How caused?
6. What is the morphology of Bacillus mallei?

7. What diseases are caused by the following bacteria: Shiga's bacillus, Koch-Weeks bacillus, Klebs-Loeffler bacillus, Diplococcus of Neisser, bacillus of Unna Ducrey?

8. What is a trap? What purpose does it serve in drains?

9. Describe the construction of a filter for river water to be used for drinking purposes by the people of a small city.

10. How many cubic feet of air is necessary for each patient in a general hospital?

ANSWERS TO STATE BOARD EXAMINATION QUESTIONS.

Ohio State Board of Medical Registration and Examination.

June 8, 9, and 10, 1909.

ANATOMY.

1. The bones which enter into the formation of the orbit are: The frontal, sphenoid, ethmoid, superior maxillary, malar, lacrymal, and palate.

2. *Nerve supply of the stomach:* The pneumogastrics, and the sympathetic.

3. *Ligoments of the knee-joint:* Anterior, or Ligamentum Patellæ; Posterior; Internal lateral; Two external laterals; Capsular; External crucial; Internal crucial; Transverse; Coronary; Ligamentum mucosum; and Ligamenta alaria.

6. Coronary arteries, innominate, left common carotid, left subclavian, pericardial, bronchial, esophageal, posterior mediastinal, intercostals, and subcostal.

7. *Composition of bones:* (1) Organic matter (gelatin and blood-vessels); and (2) inorganic matter (calcium phosphate, calcium carbonate, calcium fluoride, and magnesium phosphate).

Bones are classified as: Long, short, flat, and irregular.

8. *Structures forming the larynx:* Nine cartilages, viz., Thyroid, cricoid, epiglottis, two arytenoids, two cornicula laryngis, and two cuneiform. The thyrohyoid membrane, cricothyroid membrane, thyroarytenoid ligaments, capsular ligaments, hyoepiglottic ligament, thyroepiglottic ligament; and, interiorly, the vocal cords.

PHYSIOLOGY.

1. *Properties of protoplasm:* (1) Irritability, or power of responding to a stimulus; (2) power of movement; (3) power of assimilation; (4) power of growth; (5) power of excretion, and (6) power of reproduction.

2. *A Neuron* is the unit of the nervous system; it consists of a nerve-cell with its processes and terminations.

3. *Ameboid movement:* The ameba puts out from its sides projections of the protoplasm; and later the whole mass flows into these projections, and thus the ameba changes its position and its shape. The white blood corpuscles and some other cells also exhibit this same movement.

4. *Capillaries* are tiny blood channels, generally consisting of a single layer of endothelial cells, and connecting the smallest arterioles with the venules. *Function:* It is here that all the changes occur which take place between the blood and the tissues of the body. Oxygen and the products of digestion and absorption are conveyed to the tissues, and carbon dioxide and waste matters are taken up and carried away from the tissues.

5. *The forces contributing to the flow of blood through the veins* are: The action of the heart, aspiration of the thorax, contraction of the muscles, and the valves in the veins.

6. *Reflex actions* are involuntary or unconscious movements, due to suitable stimuli. They depend upon the integrity of the *reflex arc*, which is a complex made up of: (1) A surface capable of receiving an impression; (2) an afferent nerve; (3) a nerve cell capable of receiving and also of sending out impulses; (4) an efferent nerve, and (5) a surface capable of responding in some way to the impulse conveyed by the efferent nerve.

7. *Digestion* is the process by which the food is converted into material suitable for absorption and assimilation.

Nutrition consists in the absorption and assimilation of such physiological principles as are necessary to preserve the normal structure and function of the body.

8. *The function of the hydrochloric acid in digestion:* "Hydrochloric acid exerts its influence in a variety of ways. It is the main agent in the derivation of pepsin and rennin from their antecedent zymogen compounds: it imparts activity to these ferments; it prevents and even arrests fermentative and putrefactive changes in the food, by destroying microorganisms; it softens connective tissue, it dissolves proteids and acidifies the proteids, thus making possible the subsequent action of pepsin."—(From Brubaker's *Physiology.*)

9. The proteids are necessary for life; they build up and repair the tissues of the body; they also supply heat and energy. A large proportion of proteid is found in: Beef, beans, cheese, fish, fowl, peanuts.

10. *To make cow's milk resemble human milk:* The cow's milk must be diluted and sugar of milk must be added. These modifications must be made in such proportions as to bring the percentage composition of the two milks as near alike as possible.

CHEMISTRY.

1. Milk consists of water and solids (Proteids, fats, sugar, and salts). These are (roughly) about 4 per cent. each of proteids, fats, and sugar in cow's milk.

The most common impurities are: (Dirty) water, microorganisms, boric acid, formaldehyde, salicylic acid, flour, arrowroot, coloring matters, etc.

2. Acids with the *ic* termination contain more oxygen than the corresponding acids with the *ous* termination. Thus: HNO_3 is nitric acid; HNO_2 is nitrous acid.

The salts from the *ic* acids end in *ate;* those from the *ous* acids end in *ite.* Thus: KNO_3 is potassium nitrate; KNO_2 is potassium nitrite.

3. The alkalies, if given just before meals, increase the flow of the gastric juice; but if given towards the end of gastric digestion, they are antacid, and neutralize any excessive acidity.

4. Water may be purified by: Distillation; boiling and filtration; and by precipitation, with the aid of an alum or ferric salt.

5. HCl is made in the human body in the glands of the stomach. *How* it is made is not known. It is supposed to be derived from the chlorides of the blood. One view is that it is due to a reaction between the chlorides and phosphates of the blood, thus:

$$NaH_2PO_4 + NaCl = Na_2HPO_4 + HCl.$$

There are other views, but the matter is not settled.

7. A calcium sulphide is a binary compound whose molecule consists of one atom of calcium and either one or two or five atoms of sulphur, CaS., CaS_2, or CaS_5. The monosulphide, CaS, is a white amorphous substance, but slightly soluble; when heated, it shines in the dark. It is used for making luminous paints, also as a depilatory.

8. *Common properties of the mineral acids:* They are acid in reaction and in taste, are irritant, and corrosive.

9. *Symptoms of carbolic acid poisoning:* Buccal mucous membrane is whitened and hardened; vomiting; burning pain in mouth, esophagus, and stomach; pulse and body temperature are lowered; the pupils are contracted; collapse, and finally death. The urine may become dark.

The treatment of carbolic acid poisoning consists in administering white of egg, sodium sulphate, or saccharated lime, followed by lavage. Alcohol is said to be antidotal.

10. *Physiological antidotes* act as such by combating the physiological action of the poison.

Physiological antidotes for strychnine: Chloral hydrate, chloroform.

MATERIA MEDICA AND THERAPEUTICS.

2. The more important official preparations of digitalis are: The tincture and the infusion. Of these the tincture is generally given for its action on the heart, and the infusion for its diuretic action.

3. Antidiphtheritic serum (dose 3,000 units) is official; tuberculin, tetanus antitoxin (dose ℥ijss to ℥v), antistreptococcic serum (dose ℥ijss to ℥v), and some others are also used.

Sera may be administered by hypodermic injection or by mouth. The use of the above mentioned sera is indicated by their names.

4. Iodides should be administered in a syrup, such as the compound syrup of sarsaparilla. No other drug should be administered with it

The iodides are incompatible with the mineral acids, metallic salts, ammonia, alkaloids and their salts.

5. As a general rule, ether would be the anesthetic of choice. But chloroform may be used: (1) in hot climates; (2) when large numbers of persons have to be rapidly anesthetized; (3) in brain surgery; (4) in labor; (5) in patients who are known to take ether badly; and (6) in the conditions mentioned below, in which ether is contraindicated.

The following contraindications for ether and chloroform are from Hare's *Practical Therapeutics:* "Ether should not be used by inhalation in bronchitis or acute nephritis because of its irritant properties; in peritonitis

or gastritis, because it is apt to induce vomiting; in aneurysm or in the presence of marked vascular atheroma, because it may rupture a blood-vessel by raising arterial pressure; nor in diabetes, lest it produce diabetic coma; and if anemia is present and an examination of the blood shows that the hemoglobin is below 50 per cent., the use of the drug should be avoided if possible.

"*Chloroform* is not to be used in cases of fatty heart or dilatation of the heart, in those with a known idiosyncrasy, nor in the so-called lymphatic persons with overgrowth of lymphoid tissues, as, for example, adenoids. In the latter case it is particularly apt to cause sudden death. In valvular disease of the heart chloroform may be used with caution, although ether is preferable. Given a case of valvular disease that must be subjected to operation, the chances are bettered with an anesthetic than without it, as the pain and mental shock are worse for the heart than is the anesthetic."

7. *Symptoms of continued use of cocaine:* Emaciation, mental and moral impairment, delusions, circulatory disturbances, and insomnia.

Treatment consists in sustaining the patient's strength; nitrite of amyl or ammonia may be inhaled; belladonna and caffeine have been tried; stimulants are indicated.

9. *Alkaloids* are organic nitrogenized substances, alkaline in reaction, and capable of combining with acids in the same way that ammonia does.

General properties of alkaloids: Alkaloids are of two kinds, volatile and fixed. The volatile alkaloids are liquid, readily volatile without decomposition, and consist of C, H, and N. The fixed alkaloids are for the most part solid and crystalline, not, or only partially, volatile without decompositon, and consists of C, H, N, and O.

Most of the alkaloids are alkaline in reaction, of a bitter taste, and of white color.

Most of the alkaloids are nearly insoluble in water, but are soluble in alcohol, chloroform, ether, and benzine; their salts are generally soluble in water and alcohol, but insoluble in the other solvents just named. They combine with acids to form salts in the same way that ammonia does.

PRACTICE OF MEDICINE.

1. In diphtheria, pneumonia, scarlet fever, and empyema, the leucocyte count is probably over 25,000.

2.

HYDRONEPHROSIS	OVARIAN CYSTS
1. Enlargement unilateral and from above downward. Growth fixed in region of kidney.	1. Enlargement at first unilateral; later symmetrical and from below upward. No fixation.
2. Expression unchanged.	2. Facies ovariana.
3. Growth usually slow.	3. Growth relatively rapid.
4. Intestines may be in front of tumor.	4. Intestines in the flanks above and back of tumor.
5. Fluid not necessarily albuminous; may contain calculi.	5. Fluid albuminous; no calculi.
6. Vaginal touch negative.	6. Tumor usually felt by vaginal touch.
7. Urine may contain pus, blood, or albumin.	7. Urine generally normal.
8. Cystoscopy shows absence of urine through ureter on affected side.	8. Urine flows through ureter on both sides.
Exceptions.—In case of a movable kidney the tumor may not be fixed.	*Exceptions.*—In case of adhesions the cyst may be fixed.

(From Dudley's *Gynecology.*)

4. In *aortic stenosis:* A systolic murmur heard over the aortic area, transmitted into the carotids, and usually accompanied by a loud first sound. Hypertrophy of the left ventricle, increased area of cardiac dullness, apex beat is displaced downward and to the left, the pulse is generally small and infrequent.

6. *Empyema is diagnosed* by: High and irregular fever, sweats, chill, diminished breath sounds and vocal fremitus, impaired mobility of chest, dullness on affected side, heart displaced to opposite side, leucocytosis. Absolute diagnosis is made by aspiration, showing the fluid to be pus.

Treatment: Aspiration, drainage, irrigation, resection of ribs (Estlander's operation), or resection of chest wall (Schede's operation).

7. In *gallstones:* The pain is in the region of the liver; it radiates to the right scapula and toward the umbilicus; chills and sweats are common; also vomiting, and sometimes symptoms of collapse and jaundice; calculi may be found in the feces.

In *appendicitis:* The pain is at first diffuse, but later becomes localized over the appendix in the right iliac fossa; nausea, vomiting, and constipation may be present; tenderness over the appendix and rigidity of the right rectus abdominis muscle are present; there is generally moderate fever.

8. *Paranoia* is a primary chronic form of insanity, occurring especially in degenerates, and marked by hallucinations and delusions which are systematized, *i.e.* exhibit a logical connection and sequence, so that the patient from his perverted ideas, in which he firmly believes, draws logical and coherent influences. (From Duane's *Medical Dictionary.*)

10. In *active hyperemia* there is an excess of arterial blood in a part, with, generally, acceleration of flow.

In *passive hyperemia* the excess of blood is in the veins and capillaries, and the flow is retarded; it is generally due to some mechanical obstacle.

DIAGNOSIS.

1. "The causes of excessive respiratory action of the abdomen—*i.e.* of the diaphragm—are found in conditions which render movement of the thorax painful, such as pleurisy, pleurodynia, or fracture of a rib; or which mechanically hinder thoracic expansion, as in double pleural effusion, calcification of the costal cartilages, emphysema (permanent inspiratory form of the thorax throwing extra work upon the diaphragm), the rare scleroderma of the chest wall, and ossifying myositis. Inaction of the thorax may also be due to paralysis of the muscles of inspiration, as in injury or diseases of the cervical portion of the cord or bulbar paralysis, or spasm of the same muscles in strychnine poisoning or tetanus." (Butler's *Diagnostics of Internal Medicine.*)

2. *A persistently frequent pulse in persons without fever may suggest:* Phthisis, exophthalmic goiter, Addison's disease, pernicious anemia, chlorosis, locomotor ataxia; also neurasthenic conditions, sexual excesses, abuse of alcohol, coffee, or tobacco.

3. *Amenorrhea may indicate:* Hysteria, melancholia, mental overwork, anemia, phthisis, nephritis, diabetes, cancer, malaria, leukemia, morphine habit.

4. *Back pressure in the superior cava* is followed by: Cyanosis of the lips and face, clubbing of the fingers, and (with tricuspid regurgitation) a systolic jugular pulse.

5. *The physical signs of pyloric stenosis* are: The stomach may be observed to be dilated, a tumor may be felt at the pylorus, splashing or succussion sounds may be obtained.

SURGERY.

2. *The united fractures are most commonly found* in: Patella, olecranon, coracoid process, humerus, neck of femur.

Causes: Wide separation of the fragments, interposition of soft parts, want of rest, defective blood supply, bone disease.

Treatment: Continued immobilization in plaster of paris, with use of limb (if it does not increase the displacement); rubbing the ends of the bone together; refreshing the bony ends and fixing by plates, or wires, or screws; or retentive apparatus.

4. *Injuries common to knee joint* are: Sprains, dislocations, penetrating wounds, fracture into the joint, fracture of patella, rupture of quadriceps tendon or of ligamentum patellæ, displacement of semilunar cartilage.

5. *The early symptoms of hip-joint disease* are: Night cries (in a child); lameness in the morning; a slight limp; tendency to become tired on slight exertion; wasting; spasm; pain; swelling; and deformity (either real or apparent).

Treatment: In the early stages, rest in bed is indicated, with extension; also tonics, restoratives, fresh air. If necessary, the limb should be straightened and put up in plaster-of-paris, or a brace or other mechanical appliance should be used. Intraarticular injections of iodoform have been recommended. Resection of the hip may be necessary.

7. *The diagnostic symptoms of tuberculous kidney* are: Frequent micurition, with pus, and sometimes blood in the urine; pain and tenderness over the kidney, enlargement of kidney; chills, fever, and sweats; tubercle bacilli may be found in the urine; the cystoscope will show a retracted ureteral meatus on the affected side; the symptoms are not made worse by movement or improved by rest.

OBSTETRICS.

1. *The factors in the expulsive forces of labor* are: The uterine contractions and the contractions of the diaphragm and of the abdominal muscles.

2. At two months none of the certain signs would be present. Cessation of menstruation, in a woman who had previously been regular, with morning sickness, increased frequency of micturition, softened cervix and breast signs (enlarged breast, more prominent veins, deeper pigmentation) would all be very suggestive, especially in a primipara.

7.

UTERINE MYOMA	OVARIAN CYSTOMA
1. Slow growth.	1. Usually more rapid growth.
2. Facial expression unchanged. Face may be full and flushed; later pale from hemorrhage.	2. Facies ovariana.
3. General health usually unimpaired except from loss of blood, if submucous or mural; may be painful.	3. General health early impaired from emaciation. Not painful.
4. Abdomen usually very asymmetrical from irregular shape of tumor.	4. Abdomen more symmetrical, especially when tumor is large.
5. Abdominal veins not usually enlarged.	5. Usually enlarged, especially in large polycysts.
6. Action of kidneys normal.	6. Kidneys less active.
7. Usual menorrhagia.	7. Menstruation unchanged or diminished.
8. Elasticity, not fluctuation. No percussion wave.	8. Fluctuation marked. Percussion wave marked.
9. Surface firm and usually lobulated.	9. Surface yielding; in monocysts, regular; in polycysts, irregular.
10. Vaginal touch and conjoined examination show tumor dense and firm, and, unless pedunculated, continuous with uterus. Uterus large and heavy.	10. Uterus normal, except displacement from pressure. Tumor compressible, fluctuating, detached from uterus.
11. Uterine cavity much elongated.	11. Not materially elongated. (This is a most important diagnostic point.)
12. Uterus moves with tumor.	12. Does not move with tumor.
13. Negative results from aspiration, but aspiration is not advised.	13. Positive results from aspiration, but aspiration is not advised.
Exception.—A subperitoneal myoma with a long pedicle moves independently of the uterus, and the uterine cavity is not necessarily lengthened. If the myoma has degenerated to a fibrocyst there will be more or less fluctuation, and aspiration may yield positive results.	*Exception.*—A cyst with semisolid contents yields negative results on aspiration. Fluctuation, if present, is indistinct, and percussion wave is absent or indefinite.

(From Dudley's *Gynecology.*)

10. *Treatment of senile vaginitis:* When the subjective symptoms are not annoying, do little or nothing. Vaginal douche with hot normal salt solution; or corrosive sublimate solution (1 in 10,000), followed by saline solution; tampons of ichthyol and glycerin (1 to 10); ulcers may be painted with a mild solution of silver nitrate occasionally.

DERMATOLOGY, SYPHILOLOGY, AND DISEASES OF THE EYE, EAR, NOSE, AND THROAT.

1. *Scabies* in a contagious animal parasitic disease, due to the *Sarcoptes scabici*, characterized by burrows and a multiform eruption, and attended by severe itching. The eruption usually occupies certain areas where the skin is thin; these are the interdigital spaces, the flexor surface of the wrist and arm, the anterior and posterior axillary folds, the mammæ and nipples (in women), the umbilicus, the buttocks, the penis, the inner side of the thighs and legs, and the toes. The face is exempt except occasionally in infants. The itching is intense and worse at night. The affection is curable, but dermatitis may result from over treatment.

Treatment consists in a thorough scrubbing with soap and warm water, followed by friction to dry the skin, and the application of sulphur ointment; the latter to be repeated morning and night for three days. The whole process may need to be repeated one or more times.

4. *Syphilitic skin eruptions* are characterized: By not itching; by being of a coppery or raw ham color; by being painless; by polymorphism, macules, papules, pustules, etc., being present at the same time; by being generally symmetrical.

PATHOLOGY, BACTERIOLOGY, AND HYGIENE.

2. *Kinds of tissue degeneration:* Cloudy swelling; fatty infiltration and degeneration; amyloid, mucoid, hyaline, and colloid degenerations; glycogenic infiltration; hydropic; and bone caries.

3. *Four possible sequelæ of peptic ulcer of the stomach:* Hemorrhage, perforation, gastroduodenal fistula, peritonitis.

7.

BACTERIA	DISEASES CAUSED BY
Shiga's bacillus.	Dysentery.
Koch-Weeks bacillus.	Conjunctivitis.
Klebs-Loeffler bacillus.	Diphtheria.
Diplococcus of Neisser.	Gonorrhea.
Bacillus of Unna-Ducrey.	Chancroid.

8. *A trap* is a bend in a pipe; it contains water, and serves to prevent the passage of sewer gases into houses.

10. The air space for sick people should be at least one-fourth more than that allowed for well people. Hence, 1,000 cubic feet + 250 cubic feet = 1,250 cubic feet of space should be allowed in hospitals for each person. Of course, as much more than this as is possible, provided it is properly warmed and distributed, is desirable.

BULLETIN OF APPROACHING EXAMINATION †

STATE	NAME AND ADDRESS OF SECRETARY	PLACE AND DATE OF NEXT EXAMINATION	
Alabama*	W. H. Sanders, Montgomery	Montgomery	Jan. —
Arizona*	Ancil Martin, Phoenix	Phoenix

RELIEF OF URINARY AND GENITAL CONDITIONS THROUGH SURGERY OF THE SEMINAL VESICLES;

INCLUDING A SUMMARY OF THE AUTHOR'S EXPERIENCE.*

By EUGENE FULLER, M.D.,

NEW YORK.

PROFESSOR OF VENEREAL AND GENITOURINARY SURGERY NEW YORK POST-GRADUATE MEDICAL SCHOOL, VISITING GENITOURINARY SURGEON TO THE CITY AND POSTGRADUATE HOSPITAL, ETC.

IN my early years as a devotee of genitourinary surgery the fact became strongly impressed upon me that surgical thought and attention had hitherto been focused almost wholly on the urinary tract, the genital tract, with the exception of the testicle and epididymis, having been scarcely considered. The surgeon would in those days occasionally make a rectal examination to determine the condition of the prostate, but palpation of the seminal vesicles was rarely attempted or even considered. The text-books of the time made mention of a class of gleets which were either incurable or at best got well only after the individual affected had in despair given up the surgeons. Sexual disturbances rarely received any serious attention.

Feeling that this neglect of the genital tract accounted for the fact that a considerable percentage of patients failed to obtain relief, I began systematically to make a digital examination per rectum of the prostate and seminal vesicles of all genitourinary patients, and as a result introduced the procedure of stripping the seminal vesicles as a method of cure for inflammatory and atonic conditions of these organs.† This method of treatment is technical, requires much practice in the rectal touch, a pliable finger, and judgment on the part of the surgeon in regulation of the amount of pressure to be employed. In my hands it has proved eminently satisfactory and curative in the great majority of cases. It fails in some very chronic and advanced cases of seminal vesiculitis, especially where the lesion is so extensive as to involve not only the seminal vesicles themselves but also the outlying tissues in the post-prostatic space.

An argument against the treatment in cases where the lesion is severe lies in the fact that many months are required in such cases to effect a cure. Certain individuals cannot devote a long time to treatment and so cannot be cured in that manner. To some cases the stripping treatment is not adapted and if tried gives poor or bad results. To this class especially belong the highly inflammatory cases.

As a radical surgical procedure to be employed to effect a cure in such cases of seminal vesiculitis as were not amenable to the more palliative method of treatment just mentioned, I presented to the profession in 1901 my operation of seminal vesiculotomy.* In that article, which was in the nature of a preliminary report, only five cases having then been operated upon, the procedure was described.

Since then, as the result of large experience, I have modified the technique in a few details. In order to make clear my present method of operating I will quote from the original article just mentioned the procedure there described, introducing in that description the later modifications:

"In the first place, it must be remembered that the perineal and pelvic structures to be submitted to operation are soft, yielding and elastic. In order

FIG. 1.—The position of the patient in the author's operation.

to facilitate an accurate dissection through such tissues they should be made to assume as stable a position as possible, and that can only be accomplished by putting them on the stretch, thus making them taut. This can be accomplished by flexing the thighs sharply, as in the extreme lithotomy position. The patient with his thighs so flexed is put belly downward on a Trendelenburg table, the buttocks protruding somewhat over the end while the flexed thighs straddle the table. The end of the table is then inclined upward quite sharply."

Although the bodily position represented in Fig. 1 is the same as that I now employ, I found that it was very difficult to maintain the body in position with that kind of table and with the thighs hanging straddled over the sides of the table. I have consequently abandoned that arrangement, and now have my patient on a perfectly level table in the

*Read before the American Urological Association at the Atlantic City meeting, June 7, 1909.

†"Seminal Vesiculitis," *Journal of Cutaneous and Genito-urinary Diseases*, New York, Sept., 1893. "Persistent Urethral Discharges Dependent on Subacute or Chronic Seminal Vesiculitis," *Ibid.*, New York, June and July, 1894. "Disorders of the Male Sexual Organs," Lea Bros., 1895.

*A new operative method to expose the seminal vesicles and prostate for purposes of extirpation and drainage. *Journal of the Medical Association*, May 4, 1901.

knee-breast position with the knees well separated, both the thigh and knee joints being sharply flexed. Fig. 2 represents this modified position. While the operation is in progress it is necessary that an attendant should stand at either side to see that the flexed position of the patient be maintained, and to

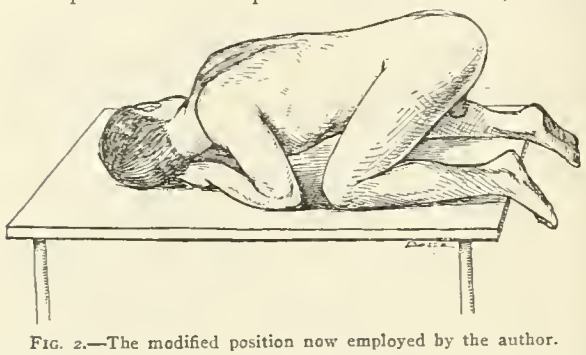

Fig. 2.—The modified position now employed by the author.

make sure that the knees do not slip off the lateral edges of the table or become approximated. In the original article I stated: "An antiseptic, lubricated cotton tampon, to which a tape is attached, is then pushed into the previously cleansed rectum, well up into the region of the sigmoid, in order to guard against bowel leakage during the operation." This tampon I have now dispensed with, having found it not only more or less in the way of operation but also unnecessary. The bowel after free catharsis is carefully irrigated shortly before operation with physiological saline solution.

"The next step is the external incision. This consists of two somewhat converging longitudinal cuts, which are connected at their dependent and proximal extremities by a transverse cut. The longitudinal cut to the operator's right begins a little above the border of the patient's coccyx and just inside the body of his right ischium, and extends downward and slightly inward, keeping just within the border of that bone, passing the tuber ischii and ending somewhat below that tuberosity at a point laterally and about three-fourths of an inch anteriorly to the anterior margin of the anus. The longitudinal cut to the operator's left corresponds exactly to the one just described, it lying in like manner along and just within the body of the left ischium. The transverse cut connects the converging ends, dividing the perineum transversely about three-fourths of an inch anterior to the anterior margin of the anus. Fig. 3 shows the line of the incision. The line of incision being so marked the next step is to incise deeply along the longitudinal cuts, going through the fatty tissue of the ischiorectal space and dividing above a few of the lower fibers of the gluteus maximus muscle. The transverse cut is then deepened, the anterior layer of the deep fascia being cut through. Great care should be taken in cutting down transversely to keep sufficiently away from the anus to avoid wounding the sphincter muscle. The forefinger of the operator's left hand should next be inserted into the rectum, the ball of the tip being turned downward against the anterior rectal wall, while the corresponding thumb presses against the loosely dissected rectum, the hand at the same time exercising upward traction as illustrated in Fig. 4. The gut is thus held up in the grasp of the thumb and forefinger, while with his right hand the operator employs the knife to dissect more deeply, cutting through the levator ani muscle and the visceral layer of the pelvic fascia. It must be borne in mind, in this connection, that the pathway of the dissection, which is between the urethra and rectal wall, is very narrow. The forefinger in the rectum acts in this deep dissection as a most important guide. The stroke of the knife in making it should be inward and at the same time toward the rectal wall. The tip of the finger should always be moved so that it is just behind the portion of the rectal wall where the dissection is being made. This being done there is no danger of perforating the rectal wall, and at the same time the direction of the dissection, keeping along close to the rectal wall, is such that the urethra escapes damage. In case the lower portions of the lateral incisions have not been deep enough to sever the fibers of the levator ani muscle they can now be made so. This accomplished, the rectal flap of the wound can be still further raised. The knife is then for the time being discarded and the operator's right forefinger inserted along the dissection, keeping just below the rectal wall till it passes through the cut in the visceral layer of the pelvic fascia and enters the lymph space which lies between the prostate and the rectal wall. This space being reached, the left forefinger should also be passed in alongside the right and the path of the wound over the prostate divulsed by separating the fingers. This much accomplished, it is comparatively easy, by a continuance of this separating process with one or both fingers, to strip the loose rectal connections off from the seminal vesicles and the posterior bladder wall, leaving those parts exposed to direct surgical attack."

The foregoing account was the original description of the operative steps taken in making the dissection. I find at present that it is not necessary to lift up the rectal flap by grasping it between the left thumb and forefinger, as shown in Fig. 4, in order to facilitate the deep dissection. In fact, I now consider my original procedure in this particular somewhat faulty, in that such traction tends to put the bowel wall on the stretch, thus increasing the danger of its being perforated by the tip of the left forefinger. I find that it is unnecessary to lift up the bowel wall at all. I make the same use of the left forefinger as originally described but do not use the left thumb. If only the lateral incisions are made deep into the ischiorectal fat the natural elasticity of the rectal tissues will cause sufficient retraction of the rectal flap, as the transverse dissection proceeds, to obviate the necessity of any upward traction. One and a half to two inches pre-

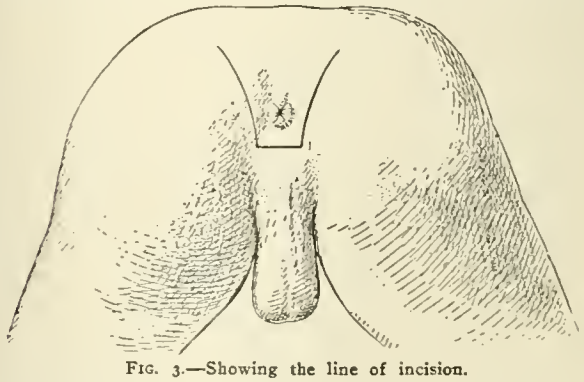

Fig. 3.—Showing the line of incision.

sents the amount of natural retraction, as illustrated in Fig. 5. Besides greatly minimizing the danger of accidental perforation of the rectal wall this retraction satisfactorily exposes the track of dissection. In my present procedure also after the knife has been discarded and the finger tip employed in

the deep lymph space to separate the rectal wall from the prostate and the seminal vesicles, I do not divulse the wound with both forefingers nor do I use both these fingers together in the track of dissection. I accomplish all this work with the right forefinger alone, and all the while the right fore-

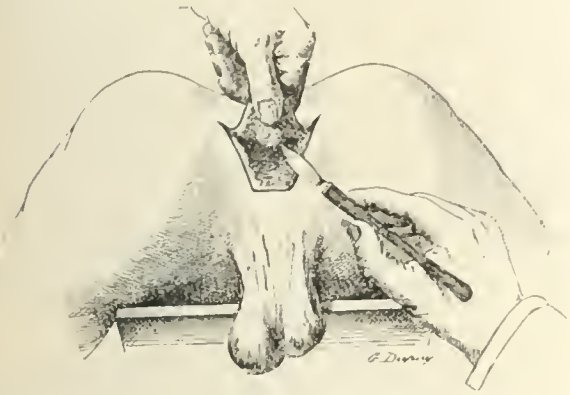

Fig. 4.—The manner in which the dissection is accomplished.

finger tip is peeling the rectal wall off from the lower structures the left forefinger tip maintains its position in the rectum, guiding, as it were, the lower finger in its work and preventing it from directing the dissection pressure against the rectal wall, thus endangering perforation. As the rectal wall only separates these two fingers, it is easy to appreciate the distinctness with which the left finger tip can feel the right as it accomplishes its work of separation. The rectal wall having been thus separated from the seminal vesicles the left forefinger is withdrawn from the rectum while the tip of the right forefinger is maintained in the dissection and made to press gently but firmly over the apex of the right seminal vesicle. A long, grooved director is next passed by the free left hand along and under the right forefinger until the end of the instrument reaches the apex of the right seminal vesicle and lies just under the right finger tip. The left hand then holds the director firmly in that position, while the right finger is withdrawn. The right hand then takes a scalpel, the blade of which is passed along the groove of the director until the point of the knife enters the apex of the seminal vesicle (Figs. 6 and 7 illustrate this procedure). After the point has so entered, the shaft of the scalpel is lowered and a free cut of about one and one-fourth to one and one-half of an inch is made with the belly of the blade along the course of the seminal vesicle, freely laying open the cavity of the organ. This cut is made with the belly of the blade rather than with the point of the scalpel, for if made with the point the incision might be accidentally too deep, the floor of the bladder being opened. The incision so made is then divulsed with the finger tip, thus widely opening the sac cavity. By an exactly similar procedure the cavity of the left seminal vesicle is next opened. The cavities thus opened can be exposed with the finger tip and, if found filled with granulation tissue, curettage can be employed. Oftentimes the finger nail may be most efficient for this purpose, although, in advanced instances, a sharp steel instrument may be necessary. Seminal vesiculotomy is not a bloody operation; no vessel, as a rule, of sufficient size to require a ligature being encountered. The cavities of the seminal vesicles so opened are each separately packed with gauze, the end of each packing being left protruding from the external wound. Two soft rubber drainage tubes are then placed between the gauze packing and the rectal wall. The lateral edges of the incision are next brought into natural apposition by sutures, the transverse portion of the cut only being left open for the ends of the drainage tubes and the gauze packing. In the after treatment no irrigation into the ends of the tubes is advisable. The gauze is removed at the end of the fifth day; the drainage tubes at the end of the ninth or tenth day. The bowels are moved daily, to guard against rectal fecal distention. In some cases urinary retention follows operation; consequently, the surgeon should be prepared to have a soft catheter passed if necessary. There is generally little systemic disturbance after this operation. A bulky gauze dressing held in position by a T bandage is the form of external dressing employed. The operation generally necessitates a stay in a hospital of three weeks, the first two weeks being in bed.

I am generally asked the two following questions by all patients before operation: (1) "Is the procedure dangerous to life?" (2) Does the operation tend to destroy or injure the sexual power?"

In answer to the first, I can truthfully state the operation is not dangerous. I have so far performed it 126 times with no mortality at all. The answer to the second is that the operation tends to preserve and strengthen the sexual power rather than the contrary. No portion of the sexual apparatus is removed by the operation; the seminal vesicles, natural cavities, being simply opened and given the benefits of surgical drainage to rid them of chronic inflammation. No new surgical principle is introduced in this operation. Other natural cavities, such as the urinary bladder, the renal pelvis, the gall-bladder, the mastoid, etc., have long and

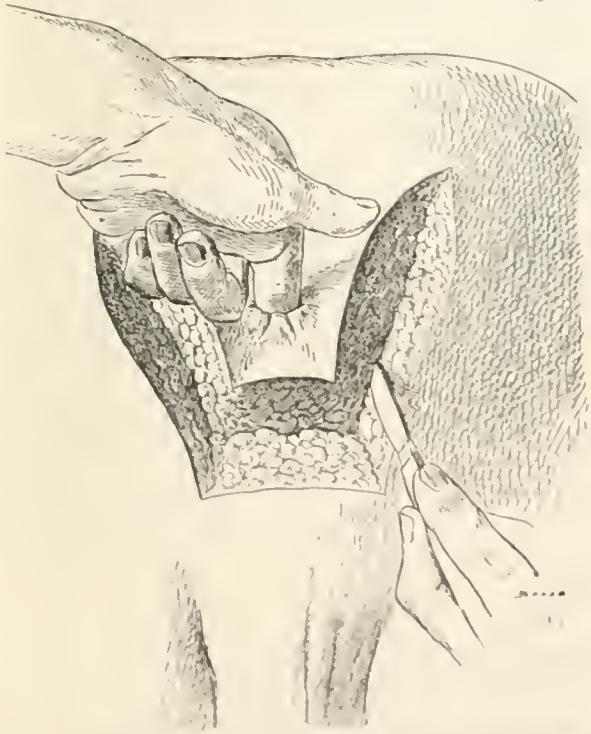

Fig. 5.—The present method of accomplishing the dissection without using the thumb to raise the rectal flap.

generally benefited from surgical drainage, consequently why is it not natural to suppose that surgical drainage of the seminal vesicles should not likewise be beneficial? The obstacles which stand in the way of a general adoption of this operation by the profession are the surgical problems it presents.

Consequently, I expect, its application will be confined somewhat to surgeons who particularly interest themselves in the genitourinary direction. In the first place, the surgeon should be skilled in the rectal touch so that he can thereby not only differentiate in diseased conditions the prostate from the

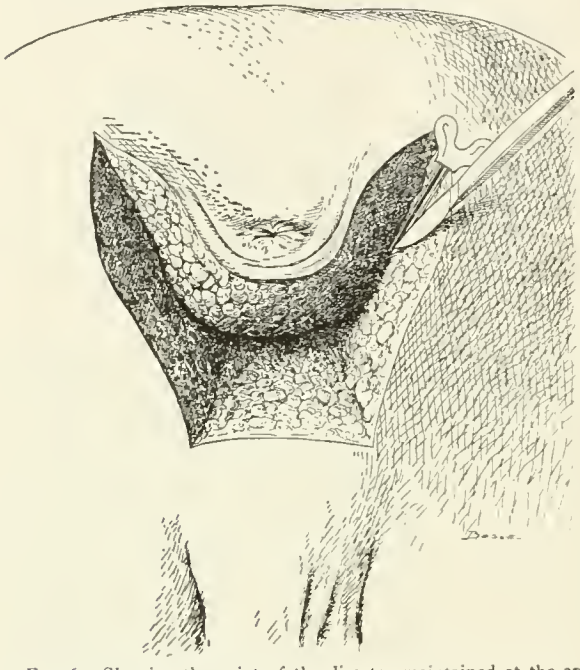

Fig. 6.—Showing the point of the director maintained at the apex of the right seminal vesicle, while the scalpel is passing along the groove preparatory to incising the organ.

seminal vesicles, but also be able to definitely locate the seminal vesicles and to appreciate the grade and quality of existing inflammation. The operation in its performance depends much, as does litholopaxy, on the sense of touch, rather than on that of sight. Guyon has often said that a genitourinary surgeon should see, as it were, with his fingers. Again, the dissection required calls not only for a good knowledge of the anatomy of the part, but also for skill in the use of the knife, as the path of dissection between the bowel and the urethra and the bladder is narrow. Still, after practice, the operation should not be looked upon as difficult or tedious. Preliminary practice on the cadaver ought to render one otherwise fitted, fully capable of performing it.

The clinical symptoms which seminal vesiculotomy may be called upon to relieve are numerous and varied. They can be grouped under the headings of urinary, genital, and generalized. In most instances careful questioning in getting clinical history will disclose the fact that symptoms belonging to two, or perhaps all three, of these groups, exist in a given case, although the chief or troublesome symptom or symptoms may be confined to one group only.

The urinary symptoms may consist of chronic or relapsing urethral discharge, shreds, pus, or bacteria in the urine, frequent painful or difficult urination, and, at times, even retention. The genital symptoms vary greatly and depend on the quality and nature of the lesion existing in a given instance in the seminal vesicles. Thus in acute inflammatory conditions there is apt to be great and painful excitation of the sexual function, aside from localized pain generally referred to the deep perineum, less frequently to the rectum, the neck of the bladder, the suprapubic or inguinal region, or to the sacrum. There may be frequent and largely uncontrollable priapism which is generally painful. At night especially is this symptom apt to be annoying, the patient stating that he is repeatedly awakened by that cause. Emissions, frequently painful, sometimes bloody in character, and followed by mental depression and nervous disturbances, are often a feature. Sexual craving, often leading the individual to excesses, frequently exists, but if the surgeon makes inquiry of such a patient, he will find that little or no satisfaction or relief follows the sexual act. In fact, it is often found that the exercise of the function simply serves to increase an uncomfortable and distressing condition of sexual craving. As the case becomes more chronic, the sexual symptoms enumerated progressively decrease in intensity, and others appear, such as sexual weakness, premature ejaculation, feeble or incomplete erections, and loss of sexual desire or ambition. Absolute impotency and entire loss of power are associated with the very chronic cases of seminal vesiculitis.

The generalized symptoms can be subdivided under the headings of neurasthenic—or nerve reflex—mental, and rheumatic. Seminal vesiculitis has the same effect on the nervous organism of the male that ovarian inflammation has on that of the female. If an individual be naturally phlegmatic, few or no such symptoms may coexist. In a highstrung person, however, they are markedly in evidence. The symptoms of neurasthenia are so well known that it is hardly necessary to detail them in this connection. When, however, a young or middle-aged man comes under my observation with marked symptoms of neurasthenia or hysteria, I invariably examine him both clinically and physically with reference to his sexual function and his seminal vesicles, and it is rare indeed when I do not discover the coexistence of a marked lesion of the seminal vesicles. The mental symptoms associated with this condition are in the nature of depression, confusion, apprehension, and melancholy.

The rheumatic symptoms are very important. They are occasioned by a systemic absorption from

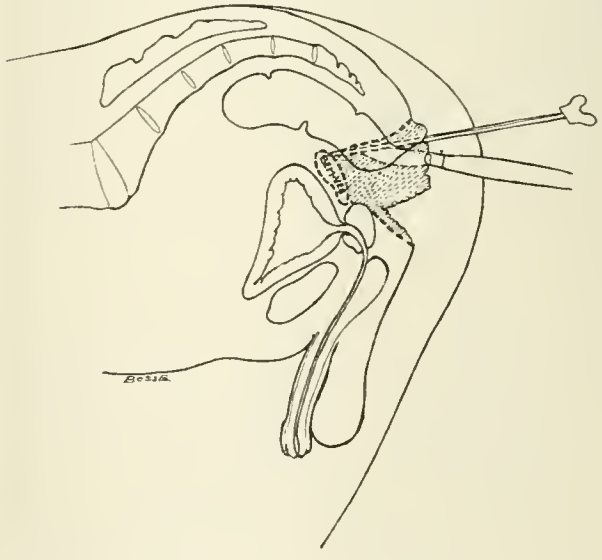

Fig. 7.—A schematic section to show the position of the director and scalpel with reference to the seminal vesicle.

a focus of seminal vesicular inflammation. The old term, gonorrheal rheumatism, is the one usually employed to describe this form of trouble. This nomenclature is, in my opinion, unsatisfactory and more or less erroneous. I make this statement because this form of rheumatism can exist entirely in-

dependent of the gonococcus. I have observed rheumatism of this description associated with a very chronic seminal vesiculitis, in a patient who had never had either gonorrhea or even sexual intercourse. There was a streptococcus involvement of the seminal vesicles in this instance, and a seminal vesiculotomy with drainage relieved the rheumatism. In numerous other instances, where chronic or relapsing rheumatism, depending on the existence of a chronic seminal vesiculitis, has come under observation and been relieved by the operation mentioned, the date of a possible or probable antecedent gonorrhea has been very remote, marriage often having intervened without evidence in the clinical recital of a propagation of any infection. From these observations, and from the fact that in the acute cases the remote joint symptoms subside in the short space of twenty-four to forty-eight hours after the establishment of seminal vesicular drainage, I have been led to wonder whether some toxin, connected perhaps with the gonococcus, the streptococcus, or some other germ, may not be the direct cause for these rheumatisms, rather than any one germ or combination of germs.

As it is probably not generally evident how the many clinical symptoms mentioned can result from seminal vesiculitis, it is advisable to make some explanatory remarks, especially in relation to urinary symptoms, since these last apparently serve particularly to mislead the average diagnostician. Chronic or relapsing urethral discharge as a symptom dependent on an existing catarrhal state of the seminal vesicles, is now quite generally accepted. That reflex symptoms of urinary urgency, unaccompanied by inflammatory products in the urine, can exist as a symptom of such disease, is not as yet very generally recognized. It is, however, a common symptom. Symptoms of true cystitis, together with pus and bacteria in the urine, also are not infrequent. I especially called attention to this condition in an article entitled "Operative Cure for a Hitherto Unrelieved Class of Cystites." (*Am. Jour. of Urology*, December, 1906).

"In the early performance of seminal vesiculotomy, the operation was undertaken for the relief of the usual symptoms, chiefly of a sexual nature, which accompany chronic inflammatory involvement of the seminal vesicles. In the study of the results of these cases I found incidentally that in a number of them symptoms of cystitis, which had coexisted with those of a sexual nature, spontaneously disappeared after convalescence from the operation. This fact led me to make a careful cystoscopic study of the bladder in a series of cases of seminal vesiculitis. I found as a result that in those of them where the bladder was involved, the lesion was confined to the base of the organ, in fact to that part of the structure lying over the seminal vesicles. In some of them where the inflammation about the seminal vesicles had been extensive, I found, likewise, that the inflammation invading the base of the bladder had been extensive and had extended further than the underlying portions of the seminal vesicles. In all these cases the other portions of the bladder were normal or nearly so in appearance. From these cystoscopic studies it seems reasonable to infer that the lesions of the vesical bases accounting for the cystites were really peripheral ones, the center foci for which were the infected seminal vesicles, the germs in the bladders having penetrated the intervening tissues from the cavities of the seminal vesicles. In other words, I classed the bladder inflammations as localized pericystites. In mild cases, the cystoscope showed the vesical mucous membrane of the area involved, red, infiltrated and edematous, while in the severe types, granulation tissue had in large measure taken the place of the mucous surface. Here and there on these granulations would be pus flocculi, films of inflammatory exudate and spots of hemorrhage. In some of the advanced cases, the least instrumental contact with the surface granulations was sufficient to provoke a fairly free hemorrhage. On one of them a triple-phosphate crustation had formed. As a result of these investigations, I felt confident that a cure of this form of pericystitis would follow spontaneously after the operative elimination of the chronic infection in connection with the seminal vesicles. Acting on this conviction, I have cured through seminal vesiculotomy a number of these cases, all, in fact, on which I have so far operated."

In that article there followed a detailed clinical report of four such operative cases.

Retention of urine, as a symptom, occurs generally in connection with acute suppurative cases of seminal vesiculitis where the periseminal vesicular loose tissues become invaded by a purulent or serous exudate, the inflammatory process having penetrated the sac walls. An extensive tumefaction occurs in the pent up post-prostatic space between the trigonum and the rectal wall. This tumefaction is frequently sufficient to cause retention, exactly in the same manner as can prostatic hypertrophy. This action is generally observed in connection with acute gonorrhea, wherein the infection runs a virulent course. In my article, "Operative Surgery Applied to the Seminal Vesicles," (MEDICAL RECORD, May 21, 1904), there is recorded a detailed clinical history of five such cases, these having occurred among my first 21 instances of seminal vesiculotomy.

Little more will be here said in further explanation of the genital symptoms, not because these symptoms are not most important, but because after the brief description of them already given their relation to seminal vesiculitis ought to be understood.

Where nervous and mental symptoms predominate, mistakes in diagnosis are frequent. Such patients, perhaps, as a rule, consult a physician rather than a genitourinary surgeon, and in a recital of their symptoms no special mention is apt to be made of genital derangements unless such facts are brought forth as the result of direct questioning from an alert consultant. Many times I have found individuals supposed to be suffering from sciatica, lumbago, nervous dyspepsia, inflamation of the appendix, neuralgia of the testicles, and other allied pains, to in reality have seminal vesiculitis, a cure of which relieved them of the reflex symptoms causing complaint. The worst forms of mental and nervous disturbances dependent on this lesion are apt to occur in the cases of young men of an average of twenty-five, the commencement of their seminal vesiculitis having occurred at or before puberty. The appreciation of this fact led me to write an article entitled "A Plea for the Sexual Protection of Young Boys" (*Am. Jour. of Dermatology and Genito-Urinary Diseases*, St. Louis, vol. xvi., No. 9), in which the following clinical description is given: "In my clinics and practice it is not uncommon to encounter young men of an average of twenty-five so wrecked nervously and mentally that they can at best barely support themselves by their own exertions, whereas, in most instances the story

is that they cannot apply themselves sufficiently to follow any employment. It is generally found that any degree of sexual excitement seems, in the patient's opinion, to aggravate the nervous and mental symptoms complained of. Sexual power has, as a rule, been so much impaired that sexual intercourse is impossible, or at best very imperfect. There is more or less mental confusion, lack of initiative, bashfulness, difficulty in suppressing emotion, shyness, and melancholy. The surgeon's first impulse on seeing such a case might be to class it as one of congenital weakmindedness associated with masturbation, and to turn it hurriedly aside as incurable, and consequently uninteresting. Many cases, with these general symptoms, do belong to that class, but there are others that do not, and it is these others that now demand attention. In this latter class it will be found from an investigation of the early clinical history that the patient as a young boy was strong, mentally alert and, as a rule, good looking and generally attractive.

"At an early age, ranging from eleven to fourteen, there will be a history of the commencement of sexual intercourse, a mature woman having been the offender and instigator of the practice. It will be further learned that the woman, for her own gratification, taxed the boy excessively and over a considerable period. The injurious effects of thus taxing the sexual function before puberty may not in the clinical history immediately show themselves. But it will be found that the boy, as he approaches puberty, will have become dull and apathetic in his studies, and of uncertain stamina mentally. There may or may not be a history at this time of some masturbation. There may be a story of some sexual indulgence at a later period, but by the time the age of twenty-one is reached sexual desire and force is, as a rule, pretty well lost, or if not sexual attempts or excitement are usually found to be so disturbing mentally and nervously as to cause the patient to shun, if possible, both these conditions."

Gonorrhea contracted at an early age may also be the primary factor in this class of cases. In the article just quoted, the results—highly favorable from operation in five such cases—are reported. In this connection, the study and relief of gonorrheal rheumatism has received from me much attention. In an article entitled "The Relation of Gonorrheal Rheumatism to Seminal Vesiculitis, and its Cure by Seminal Vesiculotomy" (*Annals of Surgery*, June, 1905), I reported the first cases—four in number—ever operated upon or treated in this manner. The results were extremely satisfactory. In a further report on the subject (*New York Medical Journal*, May 30, 1908), I make the following statement:

"In the acute bedridden cases the effect of the operation is most marked. In twenty-four to thirty-six hours the pain in the joints disappears, and by the fourth day the swelling. Some stiffness and some atrophy of the muscles are of course left after the rheumatic process has disappeared in these acute cases, requiring massage and passive movement.

"In the chronic cases pain disappears in a week or ten days, and at the end of two weeks massage can be prescribed. In the very chronic cases it may take two to three months of massage and exercise to limber up the joints which have been robbed of their function. In fact, one has the same problem in these cases which the surgeon has after resolution from a fracture of long standing. It is well known that in chronic gonorrheal rheumatism massage and manipulation make matters worse, whereas in these cases, convalescent after seminal vesiculotomy such treatment is beneficial, because there is no longer the systemic absorption of the toxine. One point I have noticed after operation in quite a number of these cases is that in the third week after operation there may be a mild and temporary recrudescence of the rheumatic symptoms, whereas in the two weeks immediately after operation there had been a complete recessation of all such symptoms. Such recrudescence, I take it, is due to a somewhat premature closure of the tract of the incision before a complete elimination by drainage of all the toxins has taken place."

On this account I am now very careful in these cases not to remove the drainage tubes until the twelfth or fourteenth day after the operation, provided they can be retained in position so long. Sometimes, where the healing is prompt, the tubes are forced from their position sooner. In such cases, the forcible retention of the tubes, after nature tends to expel them, is surgically unnecessary, besides being painful to the patient.

As already stated, I have to date performed seminal vesculotomy 126 times without any mortality. I have previously reported my first twenty-one cases ("Operative Surgery Applied to the Seminal Vesicles," MEDICAL RECORD, May 21, 1904). My 105 cases operated since that report I will here briefly tabulate. I group these cases under four headings, in accordance with their clinical symptoms. Thus, if the urinary symptoms are most prominent, a case is grouped under the urinary heading, although in that particular instance there may, and probably did, exist, less prominently, symptoms belonging to another clinical group.

The table is shown on page 723.

Out of the whole 126 cases 7 of them had a tubercular involvement of the seminal vesicles when operated upon or that process commenced in the part promptly after operation. No permanent benefit was accomplished by the operation in these 7 cases. In fact, had I known beforehand of the tuberculosis or the tendency thereto I would not have operated. Very likely the operation in some of these cases did harm by disseminating the tubercular focus. In suspected cases my rule is to make the diagnostic tests and not to operate in case tuberculosis of the part can be demonstrated. In one case, 73, the patient one year after operation declared he had not been in the least benefited. Case 95 left the hospital dissatisfied. This was the only case in which a phlebitis developed, the left leg being involved. Case 83 was not benefited. This man when examined in the clinic gave a long list of mental and nervous disturbances. He had a marked seminal vesiculitis. I suspected mental degeneracy. After operation the patient's behavior in the ward was so scandalous that his degeneracy became manifest.

These 10 cases are the only ones out of the whole 126 wherein the operation did not cure or was not at least attended by sufficient benefit to warrant its having been performed.

Out of the 35 cases of rheumatism operated upon, 15 were severe, acute cases; 13 of these were promptly cured and 2 radically relieved when last seen on leaving the hospital and probably cured. Three were subacute cases; 2 of these were cured; 1 of them represented a tubercular case and so was not eventually satisfactory. Two were cases representing recurring or relapsing attack. Both of

Urinary	Genital	Nervous and Mental	Rheumatic
23. Retention abscess, acute gonorrhœa—cure.	22. Impotency—cure	31. Mental depression, nervous reflexes—cure.	38. Acute—cure.
24. Persistent discharge—cure.	30. Sexual incapacity—cure.	32. Numerous marked reflexes—cure.	42. Acute—cure; in continuous good health three years after.
25. Marked symptoms of cystitis—relief.	34 Sterility and faulty sexual function—cure Impregnated wife two years after.	39. Reflex pains in back and elsewhere—cure	44. Acute—cure
26. Chronic discharge; later developed tuberculosis.	35. Sexual incapacity—cure.	40. Nervous and mental—greatly improved, wants to be operated on again for further improvement.	45 Acute—cure
27. Marked cystitis—cure.	43. Impotency—power restored.	41. Marked melancholy, reflexes—cure.	48. Severe case of considerable duration—prompt relief but later some relapse.
28. Marked cystitis—cure	47. Impotency, power restored.	58 Marked neurasthenia, temporary relief, but later tuberculosis.	50. Acute—prompt relief, some temporary relapse.
29. Discharge, bacterial urine, bladder irritation—cure.	49. Sexual incapacity, left hospital satisfactory; not seen since	63 Marked reflexes—cure	51. Severe and of considerable duration; temporary relapse from sexual excess—cure.
33. Marked cystitis—cure.	53. Impotency—cure	64. Marked mental and reflex, left hospital satisfied; not seen since.	52. Very chronic, quick relief from pain, but some time before joint movements are wholly recovered.
36. Difficult and frequent urination; threatened retention—cure.	55. Impotency—very satisfactory at discharge from hospital, not seen since.	72. Very neurotic; this proved to be a tubercular case; no relief from operation.	54. Very chronic and extensive involvement; some temporary relapse due to sexual intercourse soon after operation—cure
37. Relapsing discharge, and relapsing attacks of epididymitis—cure.	70. Sexual incapacity—cure.	73. Mental and neurotic; no satisfactory relief from operation.	56. Severe case, seven months' duration—cure, slight temporary relapse after operation.
46. Relapsing discharge and persistence of bacteria in urine—cure.	81. Impotency; left hospital satisfied.	77. Mental and neurasthenic; —cure	57. Severe case, seven months' duration—cure.
59. Relapsing discharge and painful urination—cure.	82. Impoteney; left hospital satisfied.	83. Mental and neurasthenic; this case proved one of mental degeneracy (paranoia); no improvement from operation.	61. Acute—cure.
60. Retention; seminal vesicular abscess—cure.	85. Impotency—cure.	84 Marked mental and neurasthenic from early abuse; great improvement.	66. Extremely rheumatic and generalized; much relief from operation; some relapse; patient transferred and lost from observation.
62. Very difficult urination; threatened abscess—cure.	91. Impoteney — cure married and has a child	87. Marked mental and neurasthenic; much better when last seen. Six months after operation.	67. Acute—left hospital relieved.
65. Relapsing discharge; left hospital satisfied.	95. Impotency; left hospital dissatisfied	88. Very bad mental and neurasthenic case of twenty years' standing; now very satisfactory two years after operation.	71. Many months' standing, numerous joints—cure.
68 Frequent urination—cure.	105. Marked sexual weakness; left hospital improved.	90. Marked mental and neurasthenic, dating from puberty; better but not well six months after, when last seen.	76. Subacute—cure.
69. Frequent urination and cystitis—cure.	107 Impoteney—cure, married.	103. Mental and neurasthenic, discharged improved.	78. Severe relapsing attack—cure.
74. Marked relapsing discharge and urinary disturbance—cure.	108. Impotent—cure; but wishes he were still stronger	124. Marked mental and neurasthenic from gonorrhœa contracted at puberty—cure	80. Recurring and severe; left hospital in very satisfactory condition.
75. Discharge; pain on urination; satisfactory on leaving hospital.	114 Marked sexual weakness; greatly improved; and satisfactory when last seen two months after discharge from hospital.	125. Marked neurasthenic—cure	92. Chronic involvement of hip; improved but not well three months after, when last observed.
79. Great urinary frequency with pain; urine loaded with pus and bacteria; greatly improved when seen six months after operation; urinated every 2½ hours without pain; still some bacteria in urine.	116. Marked sexual weakness; left hospital satisfied.		93. Chronic synovitis; left knee—cure.
86. Marked symptoms of chronic cystitis; marked temporary relief; later, tuberculosis developed.			94. Acute—cure.
89 Frequent, urgent and painful urination—cure.			96. Acute—cure.
98. Chronic discharge and urinary pain—cure, when seen one year after, though not wholly satisfied at time of discharge from hospital.			97. Very chronic and general involvement; in bed or on crutches eight years. Walked without crutch or cane to Acad. of Med. for exhibition four weeks after operation.
104. Chronic discharge and urinary urgency—cure.			99 Very acute—cure.
106. Urinary urgency and pain; left hospital relieved.			100. Marked acute involvement; bedridden three months—cure.
109. Great urinary frequency and pain; reports greatly relieved but not yet well, six months later			101. Acute—cure.
110. Urinary urgency and pain; left hospital relieved but later developed tuberculosis			102 Subacute; improved, but later developed active tuberculosis.
115. Relapsing discharge and urinary disturbance; left hospital in very satisfactory condition,			111. Marked involvement, cardiac lesion. Much improved for six months, then failed apparently from progress of cardiac lesion, and relapsing rheumatic symptoms then appeared.
118. Marked symptoms of cystitis with great pain on urination; urination very frequent; patient states he has had his bladder opened six times suprapubically and perineally, each such operation having left his condition worse—cure.			112 Very chronic involvement of both knees and ankles; left hospital much improved; six months later ankles were well but motion had not then been restored to knees. General health much better I expect this case may not have had the benefit of sufficient massage
119 Symptoms of cystitis; left hospital relieved.			113. Most chronic case of all, eighteen years progressive duration; most joints involved; general condition very bad, very marked improvement for six months following operation, now at nine months there are relapsing symptoms
123. Relapsing discharge—cure			117 Very chronic case, thighs and knees flexed latter very rigid even under anæsthesia; general conditions bad Marked emaciation; left hospital six weeks after operation, greatly improved, but in need of much massage and passive motions, not heard from since.
126. Symptoms of chronic cystitis—cure.			118 Acute—cure
			120 Subacute—cure
			121 Acute—cure.
			122 Acute—cure.

these were cured. Seven represented chronic cases of many months' standing. Severe muscular atrophic changes were not, however, as yet present. Of these, 5 were promptly cured; 1 was eventually cured, although there was a temporary relapse of symptoms a month after operation; 1 was temporarily relieved, but relapsing symptoms recurred, during which time the patient was lost to observation.

Of the 8 extremely chronic cases, most of them of years, duration, 4 were cured; 1 so greatly relieved when last seen soon after leaving the hospital that a probable complete cure occurred; 1 was greatly relieved, but at the end of six months had not yet gotten the full use of all his joints. This case is a probable cure, secondary massage only being now required. One case after six months began to fail from cardiac insufficiency due to aortic lesion; 1 case after marked relief for six months is now, at nine months, suffering considerably from a recurrence of symptoms. In this case the rheumatism had been progressive for eighteen years, and the patient's physical condition at the time of operation was very poor indeed.

252 Lexington Avenue.

CLINICAL VARIETIES OF PERIODIC DRINKING.*

By PEARCE BAILEY, M.D.,

NEW YORK.

Singled out and separate from habitual drinking is a type of alcoholism characterized by its periodicity. There are recurring attacks of intemperance and debauch, lasting from a few days to several weeks. Between the attacks, the subjects are either temperate or abstemious, or have a distinct distaste for liquor, and, for the first few years at least, bear none of the physical or mental stigmata of alcoholism. The periodic character of this variety of inebriety has long caused it to be compared with another paroxysmal disease, epilepsy. And since Gaupp, in a carefully prepared monograph on dipsomania, published in 1901, drew the lines closely together from cases of his own and from literature, there has been a gradually growing conviction that dipsomania is one of the larval forms of epilepsy. It cannot be denied that there are striking points of similarity between typical cases of dipsomania and epilepsy. Many dipsomaniacs have had convulsions and in nearly all of them may be found the same neuropathic antecedents as are met with in the histories of epileptics. Again, the action of alcohol upon a diseased or intolerant brain recalls in many ways certain symptoms of epilepsy. Intolerance to alcohol, to the results of which the Germans have given the name pathological drunkenness, is essentially epileptic in character. In it, after the ingestion of very small quantities of spirits or even beer, the individual becomes immediately flushed and excited, violent and often dangerous to others. A similar intolerance is common in epileptics, and is particularly liable to induce states of automatism in which the patient is no longer responsible. It is also frequent in other cortical diseases or degenerations, of which it may be the earliest diagnostic sign. Notable among the brain conditions in which intolerance is encountered are general paresis, degeneration of the cerebral arteries, and the state of depressed cortical function which often follows traumatic injuries of the head.

In addition to these general similarities an attack of dipsomania has certain psychic characteristics in common with those of grand mal. In both the patient becomes, for a short time before the attack, restless, anxious, dissatisfied; he reproaches himself for misconduct which had long lain forgotten; and all this without reasonable cause. This premonitory depression is constant in true dipsomania and is becoming more and more recognized as a cardinal symptom of epilepsy. In addition, retrograde amnesia, as well as amnesia for parts of the attack itself, is common in both conditions.

I have notes of a case of a young man, by nature temperate and self-controlled, in whom the attacks recurred every two or three months, sometimes less frequently. The antecedent depression was marked, and readily recognized by the family. The seizures were characterized by wild intemperance, debauch, and violence. There were distinct losses of memory for parts of the attack itself, and often also for several hours preceding the first drink. The apparently hopeless outlook in this case, which I have watched for five years; its explosive character without any psychic cause which can be ascertained, and the bad family history, seem to mark it definitely as dipsomania of epileptic nature, dependent on the same cortical irritation as causes epilepsy. Certain cases cited by Gaupp also seem equally incontestable. But such cases are rarities.

Perhaps no one sees so many varieties of alcoholism in their formation period as a neurologist practising in a large city. And of the various cases of periodic drinking I have seen, the one mentioned is the only one in which epilepsy seemed the only explanation. In the others, various causal factors pressed forward for recognition, equally or more deserving of attention than epilepsy. So I now believe that many of the so-called epileptic dipsomanias can be better explained on some other hypothesis; that what seem at first sight as epileptic explosions can frequently be reduced to certain phases of mental disease, the clinical characteristics of which soon become blurred by alcohol, or to the influence of some recurring psychic motive.

The importance of such a distinction is real, both for prognosis and treatment. True dipsomania has the same prognosis and treatment as epilepsy. Periodic drinking from other causes offers more hope for amelioration in that the cause, when found, is more get-at-able; and the case as a whole can be better understood and more rationally handled, if its causal factors are revealed.

In the listed types of mental disease, alcohol plays a varying role. It is not conspicuous in dementia precox or in melancholia. In fact, the generally received belief that mental depression causes periodic drinking seems true only insofar as it applies to depression within the limits of sanity. Under the stress of business reverses, family troubles, failing health, many become tipplers. Some become periodic drinkers. The most familiar type of this is the emotional, high strung man who gets wildly drunk, often for sev-

*Read at a meeting of the New York Psychiatrical Society on May 5, 1909.

eral days, after quarrels with his wife. But the recurring attacks of depression in which the depression is out of sane proportion to the causes alleged to have induced it—that is, the recurring depressive cycles of a manic-depressive insanity, seem rarely if ever to incite to inebriety.

In general paresis sudden attacks of inebriety are extremely common, as is to be expected from the epileptic associations of this disease. It is only when these attacks precede the physical signs or the mental deterioration that diagnosis is difficult.

In the manic phases of manic-depressive insanity, periodic drinking occurs in a way to obscure the clinical picture. In these cases the mental disease is accountable for the inebriety; but the effects of alcohol so far change the ordinary clinical behavior that it is usually only after two or three attacks that the true nature of inebriety is discovered. The two following cases illustrate this:

One is that of a young man who has been committed to Bloomingdale thirteen times in the past ten years. I appeared in one commitment, but for details of the history I am indebted to Dr. S. B. Lyon. The original diagnosis was dipsomania, and the patient's wife still believes alcohol to be at the root of all the trouble. In the beginning of the attacks while drinking, he is confused, delusional, and disordered, with more or less excitement. During the attacks, he is abusive, denounces his commitment as unjust, and threatens court proceedings. Before some of the commitments, he has been violent and made assaults. On one occasion he improved sufficiently to be removed by his mother. Two days later, he was drunk again with return of mental symptoms—he was dirty, disheveled, excited, garrulous, talked rapidly, profanely, and disconnectedly—a condition lasting several months.

Another case of this character is the following:

A man, 37 years of age when he first came under observation, had proved himself of more than ordinary business capacity. He had built up a successful business and had made shrewd investments. At college he had been regarded as intemperate. He used to go off on sprees, though not a regular drinker, and acted queerly. He was married in 1904, the bride being aware of his reputation. Shortly after his marriage, he refused for a time to speak to his wife, felt that he had lost all his money, felt that there was no hope for him, and threatened suicide. During this time he did not drink at all. In August, 1905, he began to drink and was intoxicated most of the time. At the same time, he became expansive. He bought a great many things that he had no use for, though he almost always got good bargains. A piece of real estate that he bought at this time was sold at double the price he paid for it. He would play the piano all night and would go out in his night clothes at four o'clock in the morning to feed the dogs and chickens. He kept the whole house awake with his orgies, drinking constantly; he would lock himself in the wine closet for hours at a time. Though very drunk, he appreciated fully the object of a visit from two examiners in lunacy and swore he would not be locked up. Placed in confinement, the evidences of alcoholism rapidly left him and he remained in a condition of mild reasoning mania. He reasoned with such skill that no sheriff's jury would have held him, and as he insisted on liberty or an *inquirendo*, he was discharged. He immediately became much depressed, bore no ill will toward those active in his commitment and did not drink at all. Later he resumed drinking wine at dinner without apparent ill effect and without intemperance. For three years he was well, temperate, successfully engaged in business. There was one period of excitement and intemperance which lasted several weeks, but for which no special medical attention was necessary. In the autumn of 1908, he began to drink again. He would insist on making several cocktails for everyone who called; he wrapped a napkin about his waist, served all drinks himself and said he was the butler. And, as before, would lock himself in the wine closet for hours. He developed persecutory ideas. Thought that detectives were after him, that the people on the street were making remarks about him, that people in neighboring houses were mocking him. He was placed, without commitment, in a private sanatorium. He thought he was committed and would not cross the threshold of his room in the fear that the police would get him. He had developed some important signs of alcoholism. The knee jerks were absent. And another sign, the occurrence of which as an alcoholic symptom is overlooked in most text-books, was that the pupils did not respond to light. After a few weeks' abstinence, both the knee jerks and the light reflex became normal. But he still was insane and was committed.

He was filthy in his habits and would spend his days making messes of food and odd bits of rubbish, which he called inventions. He was confined altogether for about two months, at the end of which time he was well enough to be discharged. He again became depressed, all delusions left him, and he had no desire to drink.

Both of the above cases seem to have classed themselves pretty definitely as manic phases of manic-depressive insanity. By some peculiarity of personal disposition or environment the expansive periods announced themselves by sudden outbursts of inebriety; and the resulting alcoholism marred the clearness of the mental picture. But the diagnosis was long in doubt, and by the lay mind both patients still are believed to be periodic drinkers.

Outside the sphere of well defined psychoses are many mental states touching the abnormal and characterized by instability, by impulsiveness, by excessive psychomotor reactions. It seems reasonable to think that further examination in this field may throw much light on periodic drinking.

Many of the psychic causes and the psychic effects of alcohol are interchangeable. In studying the mental states which lead to drinking, we may find one that seems important, and mark it down as an essential cause. Then, later, when observing the effects on character of alcoholism, we come again, with startling frequency, upon the same feature which caught our eye when studying causes. It may have become, perhaps, discolored, and present lines more sinister, but is none the less unmistakably the same as we knew it as a cause. Take, for example, fear. Fear as a cause of drinking has become a proverb, and

so requires neither exploitation nor comment. As a symptom, fear is disseminated through the whole clinical fabric, from the timidity of the besotted vagabond to the wild terror of the victim of alcoholic hallucinations. Thus fear is both a cause and an effect. So it is with many other of the factors busy in the genesis of this world disease. We see them as causes and, shortly afterwards, they are looking at us branded as effects. Like sheep at pasture, they jump their boundaries.

Sexual desires, wrong moral attitudes, idleness, jealousy, all appear indifferently in the category of causes or effects. And in studying the springs of inebriety, we may do worse than begin with the effects. Two of these latter—sexual excitement and jealousy—deserve especial scrutiny. The relationship which exists between the sexual appetite and the stimulant which best arouses it needs only to be mentioned to be recognized. Indiscriminate license, sexual perversion, sexual crimes, all are the results of intoxication, as readily appears in every treatise on psychiatry and legal medicine. But that certain forms of alcoholism owe their existence to sexual desire is not so well established. Normal intercourse has nothing to do with drinking; and the alcoholic hilarity which enhances the popularity of the brothel stimulates desire rather than results from it. But in periodic drinking, the generative feature stands out more closely. Procreative tendencies are themselves more or less periodic in their appearances; and their impulsive character is revealed by such degenerates as exhibitionists and curl cutters or by such imperative ideas as are found in the psychoses which result from sexual traumata in childhood. I have yet to meet a periodic drinker who was not an erotomaniac as well. One patient whom I have observed for fifteen years and who has been incarcerated in almost every institution within 100 miles of New York has never gone on a spree from which harlots were excluded. With him, contemporaneously with the idea of the initial drink, came the idea of sexual gratification. And when his family went to look him up, they would always find him in a house of prostitution, never in a bar-room. It is true that in many dipsomaniacs, the erotic ideas do not make their appearance until the stimulant has aroused desire. But in the case just described they appeared as soon as, if not sooner than, the impulse to drink; and there would be no difficulty in mustering other cases of this class. So it seems worth while to give attention to the hypothesis that some cases of dipsomania arise in the sexual centers rather than in the motor cortex—and that they are a part of a general neuropathic state and are psychogenic in origin, having no direct relationship to epilepsy. Cases in this class distinguish themselves from epileptic dipsomania in that aggressive physical violence is not conspicuous during the attacks; that the attacks can persist over many years without pronounced mental deterioration; and that, as time goes on, the attacks may become less severe and less frequent.

Another variety of periodic drinking is sometimes met with in personalities mildly paranoid, usually of the jealous type. Jealousy is among the most frequent of the psychic symptoms of chronic alcoholism, and consequently when one encounters a case of alcoholism with jealous delusions one is apt to infer that the delusions are toxic products. But this is not always correct. In a number of cases that have come under my notice subsequent events have shown that the periodic drinking was a fortuitous circumstance. The paranoid state was amplified by it, but existed independently of it—and in one case in particular was only moderately intensified by the alcohol.

This case was that of a lady of highly neurotic temperament and a jealous disposition. After having borne her husband several children she became infected with syphilis. The infection is believed to have occurred at a gynecological operation. The husband never had syphilis. But the occurrence of the misfortune intensified the wife's jealous state of mind. She wished to know everywhere her husband went; would upbraid him for his alleged attentions to other women; and frequently insulted different female members of her own family on the ground that her husband was unduly attentive to them. Her attitude toward her husband was fluctuating; at one time solicious and affectionate, at another she would work herself up into a jealous rage, upbraiding him and accusing him of all manner of improper acts of which he was guiltless. On these occasions, she would take to drink, which intensified her fury. Once she developed a typical jealous mania. She went to the police and set detectives on her husband's trail; interviewed the newspapers; threatened divorce; put a truly insane interpretation on the most trivial circumstances; said she would ruin her whole family if necessary, but that her husband should be exposed. She was drinking heavily at this time and those who saw her—police, detectives, and members of her own and her husband's family—all thought her action the sole result of drink.

Placed under treatment and being brought to realize that none of her contentions would be believed by anyone if she drank, she stopped drinking, and though she stopped abruptly, showed none of the physical signs of alcoholism. But the mental symptoms kept on in full activity, and for months afterward, although she was totally abstemious, the psychosis continued in full flower.

Another promising field for future investigation as to the genesis of periodic drinking should be among the class of emotional personalities broadly embraced by the terms Hysteria and Psychasthenia.

Throughout the clinical range of alcoholism, both of the single intoxication and of the chronic poisoning, there is disturbance in the emotional sphere. Individual feelings such as anger, grief, joy, fear, attain undue prominence, and react to stimuli too easily. This fact explains why cures, whether they be religious, "scientific," or commercial, which appeal to the emotions, are the ones which have the greatest success with the drunkard.

And as we find these psychic features as results, it would not be surprising if they also figured as causes. We know now that many obsessions, tics, morbid fears, and even certain paranoid states, had their starting points in some painful emotional experience. I believe that periodic drinking, allied in many ways to these psychasthenic or hysterical complexes, will soon be shown, in many instances, to have had a similar starting point.

I regret that no case in my records has been

analyzed from this point of view, although in one case, seen many years ago, there seemed an intimate connection between the paroxysms of drinking and certain feelings of inadequacy, which latter resulted from unfortunate surroundings in childhood. The newer methods of psychoanalysis would perhaps have shown a still closer relationship.

In closing, I would urge a careful psychological analysis of all cases of periodic drinking. It is only by such means that the proper curative measures can be unearthed. Chronic alcoholism has some right and title to be considered a disease. But dipsomania, in most cases at least, is not so much a disease as it is disorder of personality. And the treatment must be shaped to that end. Before this is possible, the defects in the personality must be laid bare. The treatment, therefore, is individualistic, varying in every patient in accordance with the results of the analysis of him as an individual.

IS LOBAR PNEUMONIA INFLAMMATION OF THE LUNGS?

By T. G. McCONKEY, M.D.,

SAN FRANCISCO, CAL.

In the introduction to Osler's "Modern Medicine" (p. xxi) Dr. Osler uses the following language: "How little actual progress has been made in clinical medicine is illustrated by what a leading practitioner, Willis, in the middle of the seventeenth century thought of such a disease as inflammation of the lungs. The essential cause was believed to be that the blood boiled feverishly, and 'sticking within the more narrow passages of the lungs engendered there an obstruction causing inflammation.'"

With due respect to Dr. Osler I shall try to show that Willis's conception of the disease is much nearer correct than is Dr. Osler's who, in his phrase, "inflammation of the lungs" evidently voices his own view and the prevailing view. I believe with Willis that whatever inflammation is found is the result and not the cause of the consolidation in the lung. To prove this I shall quote mainly Osler's Practice (last edition) and Osler's "Modern Medicine." This is written, however, not in a spirit of controversy but from a conviction that such designations as "Inflammation of the Lungs" or its equivalent "Pneumonitis" are worse than mere misnomers. Purporting to be descriptive of the essential pathology of the disease, they are misleading and therefore pernicious as names. For it can be shown that the lung condition is merely incidental to a blood infection, and further that all the cardinal symptoms of pneumonia may be present without any lung lesion.

Thanks to the laboratory workers of the past two or three years we know that in lobar pneumonia there is a pneumococcemia or better a bacteriemia. (I quote from "Modern Medicine," Vol. II, p. 556.) "It is now customary to regard pneumonia as general pneumococcus infection with the lesion in the lung as but one of the manifestations. Such a view of the disease allows a clearer conception of the clinical symptoms and the complications. That a pneumococcemia, analogous to the similar condition produced in rabbits experimentally, may occur quite constantly is indicated by a very extensive series of investigations of the blood during life. Prochaska, who found the pneumococcus in all of fifty cases examined, believes the invasion to be a constant condition in pneumonia, as does Rosenow, who obtained positive results in 160 of 175 cases in which the blood was taken at all stages of the disease. Rosenow's results show that the pneumococcus may be obtained from the blood before any physical signs are evident, thus indicating that the solidification in the lung may be but the secondary localization of a primary blood infection. * * * General pneumococcus infection without distinct localizations has been reported by Wright, Stokes, Pearce, Flexner, Hektoen, and others as the result of bacteriological examination at autopsy." This illuminating paragraph, taken from Musser and Norris's comprehensive article of over 100 pages gives one the impression of having been inserted after the general article had been written. While many other statements equally significant may be found yet they are incidental for the subject is treated from the orthodox "inflammation of the lungs" point of view. If this new view "allows a clearer conception of the clinical symptoms and complications" (and it certainly does) one wonders why the authors struggled in vain to explain the clinical symptoms from the old point of view. If this "localization" in the lung is merely secondary to a primary blood infection and not always present it is important that it should no longer occupy the lime light in our study of the disease. We know that the gravity of the disease is not commensurate with this miscalled inflammation of the lungs. Osler truly remarks that "the constitutional symptoms may bear no proportion whatever to the severity of the local lesion." Further, there is no correspondence even in point of time. No one doubts that the disease begins with the chill and rapid rise of temperature and yet at this time there are no physical signs of solidification and usually are not for thirty-six hours or longer. The mode of onset is that of a general infection and there is the positive finding of the pneumococcus in the blood before any physical signs are evident. The termination of the disease is also very significant. Osler says "the crisis is the most remarkable single phenomenon of pneumonia. With the fall in the fever the respirations become reduced almost to normal, the pulse slows, and the patient passes from perhaps a state of extreme hazard and distress to one of safety and comfort, and yet so far as the physical examination indicates there is with the crisis no special change in the local condition in the lung." Had we not been so blinded by our preconceptions and by misleading names, these facts alone should have sufficed to show that the local lung condition is relatively unimportant in accounting for the striking features of the symptom-complex we call lobar pneumonia. Even the greatly increased respiration rate, it is evident, is not dependent upon the local condition of the lung for at the crisis it falls almost to normal though the lung remains unchanged. The feeling of air-hunger in the pneumonia patient is not due to the small proportion of lung tissue out of commission but rather to an extraordinary demand for oxygen and deficient carrying power of the blood. Washbourn has shown that mice infected with the pneumococcus are dyspnoeic although pulmonary consolidation is absent. Hektoen ("Modern Medicine," Vol. II, p. 48) says "there is reason to believe that the fall of temperature with the crisis in pneumonia depends upon the somewhat sudden development of pneumococcidal and other reactions *because the pneumococci as a rule disappear from the circulating blood as crisis comes on.*" I place in italics the

significant point, for just as pneumonia begins as a general infection so it ends as soon as the blood is cleared of pneumococci.

Again, the description of the macroscopical and microscopical appearance of the solidified lung in lobar pneumonia shows that the condition is *sui generis*. The three classical stages, engorgement, red, and gray hepatiazation are not found elsewhere. The stage of engorgement lasts but a few hours, we are told, and "the capillaries of the air cells are seen to be congested and in the air cells are a few leucocytes, red blood cells, desquamated epithelial cells, small strands of fibrin and a large amount of serum." I have seen no explanation or even attempt at explanation of the presence of the red corpuscles and serum in the air cells though it surely cannot be assumed that red blood cells are normal to an inflammatory exudate. Red corpuscles being devoid of ameboid movement do not have the power of voluntary motion as do the white cells and when they are found outside the vessels it is because they have been carried out by the serum. Councilman says that red corpuscles may be found outside the blood-vessels "when the capillary circulation is very slow or when there is complete stagnation of the blood-current in these vessels." Conversely then, the presence of red blood cells outside the vessels indicates that the blood current in these capillaries is very slow or completely stagnant. This is not only a warrantable conclusion but it is an irresistible conclusion. To make the blood current very slow or completely stagnant there must be an obstruction in these capillaries. Compare this with the quotation from Willis and see how it confirms it. When the air cells become completely filled with this transudate of serum and blood cells due to the obstructed capillaries and the "small strands of fibrin" increase until they become "fibrinous plugs filling the air cells" the second stage is reached and "the lung is solid, firm, and airless." We can easily understand why the first stage is short for the transudation of the serum and blood cells soon fill the air cells and coagulation must be rapid for the blood is rich in fibrin elements and it is now in contact with air which fact we know causes prompt coagulation in normal blood. Here is the description: "The cut surface is comparatively dry, reddish brown in color and presents a uniform fine granular appearance due to the protrusion of the fibrin plugs from the air cells. * * * Microscopically, the alveoli are seen to be filled with a network of fibrin in the meshes of which are red blood cells, leucocytes, and a few desquamated epithelial cells." The stage of gray hepatization is described thus: "The air cells are seen to be filled with polymorphonuclear leucocytes, the fibrin becomes granular and is obscured by the leucocytic infiltration, and the red corpuscles appear only as shadows." Here, for the first time, we have a description of a condition approximating an inflammatory exudate but this leucocytic infiltration is not only secondary in point of time to the fibrinous plugs in the alveoli but just as certainly is it for the purpose of removal of this coagulated transudate. To speak of this entire process as "inflammation of the lungs" is to misinterpret the plainest facts or to be criminally thoughtless in the use of language. And to call the process "croupous inflammation" is scarcely an improvement. The first two stages are plainly mechanical or physical while the third stage is but the beginning of the restorative efforts of the organism which finally results in the removal of the transudate and the return of the lung tissue to normal. It is true that an inflammatory exudate is usually found on the pleural surface of the solidified lobe where it comes in contact with the thoracic pleura or that of the adjacent lobe, but this is caused by the solidification. The light, resilient, well lubricated normal lung has been transformed into a heavy, resistant, dry structure and the friction following the respiratory movements provokes a certain amount of inflammatory exudate.

The teachers of a former time rightly laid great stress upon the increased fibrin in the blood and the marked tendency of the blood to undergo coagulation. The "buffy coat" or coagulated fibrin was the criterion for the depleting methods of the days of venesection. And just as the pendulum has swung to the other extreme in blood-letting so has it in reference to the importance of fibrin in the blood. It is mentioned, but its importance is minimized. Osler incidentally mentions "the great increase in the fibrin elements" and implies that the average increase is two and one-half times the normal amount. Other writers say it may even reach five times more than normal. I have seen no attempt to account for this increase in fibrin, and yet it is capable of a very simple explanation. It is a familiar fact that the blood in pneumonia shows a marked leucocytosis except in the old or alcoholic. Virchow, who gave us the designation "leucocytosis," long ago (1858) said: "Now it is a very remarkable fact that it is very rarely that a considerable increase of fibrin takes place without a simultaneous increase in the colorless blood-corpuscles." Alexander Schmidt a few years later "found that both fibrin factors are formed from the destruction of leucocytes." Councilman says, "for the formation of fibrin it is necessary to have the white corpuscles escape from the vessels in considerable quantity and then to break down setting free the fibrin ferment." Metchnikoff says, "In blood removed from the body the white cells allow plasmane, which causes coagulation of fibrin and the formation of the clot, to pass into the liquid." In the light of these facts it is easy to account for the increased fibrin in pneumonia. Cabot studied the leucocytes in 186 cases of pneumonia and found that 137 or more than 74 per cent. had a leucocytosis varying from 10,000 to 30,000 and 17 (9 per cent.) from 30,000 to 55,000. These findings harmonize well with the statements as to increase in fibrin and it will probably be found that the increase in fibrin and the increase in leucocytes go along *pari passu*. That this leucocytosis is purposive to rid the blood of the invading pneumococci no one who has kept pace with recent teaching can doubt. Cabot e. g. says "when either the patient or the disease easily gains the upper hand there is no leucocytosis, or only a slight one; but in the much larger class of cases in which the struggle is a fierce one, leucocytosis appears, whichever way the battle results." Hektoen (p. 45) says "It is generally believed that leucocytosis in infection is beneficial not only because of the phagocytic activity of the leucocytes with respect to bacteria as well as detritus of various sorts, but also because the leucocytes may be the source of bactericidal and antitoxic substances. Experimentally it can be shown that the destruction of bacteria which are destroyed by phagocytosis (streptococci and pneumococci and human blood) is greater, the greater the number of leucocytes present in the same serum." This tendency to coagulation is thus seen to be dependent upon the curative process on the part of the organism. The following

taken from "Modern Medicine," Vol. II, p. 593) confirms this: "Experimentally it is very rarely possible to produce a pneumonia by inoculation with the pneumococcus, even when the animals are exposed to cold or when other artificial means are adopted. Wadsworth has, however, found that when animals are first partially immunized against the pneumococcus, and their resistance raised instead of lowered, intratracheal injections of pneumococci give rise to extensive lobular pneumonia or to true lobar pneumonia. He believes by this process of partial immunization the rabbit is brought nearer to the condition of man, who possesses a certain degree of resistance to infection by this organism. Thus, in man, after infection by the pneumococcus, in place of a rapidly fatal septicemia, the lungs sustain the brunt of the assault and in this situation there is set up a localized inflammation. But this process is not entirely local. In the majority, if not in all cases pneumococci gain entrance into the blood and produce a systemic infection." To get true lobar pneumonia the rabbit's resistance must be increased! How easily explained when we realize that the solidification of the lung is sequent to the curative process and how it defies explanation under the old view! The increased resistance means, of course, increased leucocytosis and this with the phagocytic activity is the present day translation of Willis's "the blood boiled feverishly."

The fact that coagulation occurs in the lungs more frequently than elsewhere is still to be accounted for. It is known that "CO_2 has some effect in hindering the formation of fibrin." Blood rich in fibrin elements would be most likely to undergo coagulation, therefore, at the point where it loses its CO_2, which is, of course, in the capillaries of the lung. It is indicative of the soundness of this view that it satisfactorily explains another obscure problem, viz., why are the lower lobes the most frequent site of the consolidation? If the lungs are the seat of election because the blood has here lost its CO_2 and is best oxygenated, it is evident that the place of election in the lungs themselves would be those lobes which are most active, which we know to be the lower lobes. I recently made an autopsy in which the apex of the left lung was consolidated and the base of the lung was found to be bound down by old adhesions, relics doubtless of a former pleurisy or pneumonia. It was evident that the apex was doing vicarious breathing and was the most active part of the lung, hence the consolidation. In showing the consolidation of the lung is incidental to the curative process it is easy to understand the late appearance or entire absence of physical signs of pneumonia, and yet the fearful mortality in the alcoholic and the aged. There is either only a tardy weak reaction or no reaction and they succumb to the overwhelming bacteriemia. (I prefer bacteriemia to pneumococcemia because other bacteria besides the pneumococcus can cause the same leucocytosis and resultant consolidation.) At the other extreme are the sthenic cases in which reaction is so pronounced that the tendency to fibrosis becomes a source of danger by the formation of antemortem clots in the heart or in important blood-vessels. I have known these chicken-fat clots to be removed from the sinuses of the dura mater, for example. They formed firm, tenacious casts and often seem completely to occlude the vessel. Osler says "in no other acute disease do we meet with coagula of such solidity." The older writers laid stress on these antemortem clots in the heart and rightly, in my judgment. We hear much about the failure of the right heart due to the increased resistance from the consolidated lung tissue, but I feel sure that as a cause of heart failure it is of much less importance than the formation of antemortem clots in the heart itself which interfere so seriously with the action of the valves.

While there is much more that could be said I believe that sufficient facts have been presented to convince the open-minded that lobar pneumonia is essentially a pneumococcemia or bacteriemia and that the localization in the lung is not inflammation, but is a process secon lary in sequence and secondary in importance. And further, that so far from Willis's conception of the disease being an example of how little they knew in the middle of the seventeenth century it is rather an example of how a sagacious man anticipated two hundred and fifty years ago the view of to-morrow.

DEFECTIVE SPEECH IN BACKWARD AND FEEBLE-MINDED CHILDREN.

By BERTHA C. DOWNING, M.D.,

LEXINGTON, MASS.

SOMETIME SUPT. OF THE EDUCATIONAL DEPARTMENT OF THE VINELAND, N. J., TRAINING SCHOOL FOR FEEBLE-MINDED. SOMETIME FELLOW ALUMNA ASSOCIATION OF THE WOMAN'S MEDICAL COLLEGE OF PA. SOMETIME HONORARY FELLOW OF CLARK UNIVERSITY.

Defective speech of the feeble-minded constitutes an important hindrance in obtaining an education. The difficulty in expressing their thoughts leads them to laziness in thought and consequent degradation. Speech and thought go hand in hand. Some one well says, "To think is to speak low and to speak is to think aloud."

The mental condition of a speaking child can best be reached by a knowledge of the extent to which language is understood and used. In the speech of *phrenasthenics*—and in this class are found most of the so-called backward children in the public schools and all the children in the state institutions for the feeble-minded—may be detected all the regressive forms of speech in a manner corresponding to the evolutionary formation of language of the modern infant.

The child cannot speak correctly because his impressive centers and expressive organs of speech are not yet completely developed. Even when these children possess a rudiment of language, they mar long words of three or four syllables because of the simple structure of their nervous system, which does not allow the extensive and complex coordination of combined movements that a long word necessitates. They, like infants, simplify the sounds and abbreviate the words. Often they pronounce the easiest or most accentuated. Sometimes, with much training they become able to add another syllable to the monosyllable. One child who had learned to recognize the doctors and to give to them the word "doctor," although he was not able to distinguish one doctor from another, or the superintendent from the attendants, was after a long time taught to say "dock." He was able with continuous exercise to form a small capital of bisyllabic words, which he pronounced, as a rule, in association with images, objects, or persons. So extreme a case as this may not come one's way often, but the illustration has its lesson.

The same long gradation that we have met with in the evolution of thought, exists in the evolution

of language, in such a way that with respect to normal language mentally defective children present, in addition to the poverty of their vocabulary, corruptions in the formation of the word, which in all cases is proof of a defect of development not only of the central but sometimes also of the peripheral organs—throat, mouth, lips, tongue—in the structure of which lies a defect of that harmonic coordination which a function so delicate and complex as that of speech demands.

Occasionally, and more especially in imbeciles, language as an outward expression is well developed, so that they pronounce all words perfectly well; sometimes, however, they do not know their signification and we have "echo-speech." This holds good for words denoting an abstraction of which they understand nothing, and in the pronunciation of which they find merely a phonetic or sensorimuscular satisfaction. Or they associate the words with a simple concrete image, sometimes even very different from those that as a rule constitute the abstract idea. So language employed by some imbeciles is not only meager, but also wanting in precision.

One child repeats the last word or the last few words of a sentence spoken in his hearing, as unconscious of the meaning as the mountainside is of the articulate sounds it echoes. Another repeats certain sounds or expressions prompted by some emotion, though the sound or expression used has no apposite relation to the emotion felt. One profound idiot when angry, happy, or hungry, would repeat "Johnny smoke the pipe, smoke the pipe." Speech here was imitative and simulated in a still greater degree intelligent speech.

The inexperienced teacher is greatly misled by these cases, not uncommon in the special classes in our public schools. A child comes to my mind who was being passed on from grade to grade. He was a mathematical prodigy, and his history, geography, and reading were all imitative, but this fact was not suspected by the teachers, though they recognized the child as "precocious."

This imitative speech shows that it is a settled fact that many ideas must be formed in order to make possible true speech. Pryer has shown in his "Mind of the Child" that the first firm association of an idea with a syllable, or with a word-like combination of syllables, takes place through imitation exclusively, but a union of this sort being once established, the child then freely invents new combinations, although to a more limited extent than is commonly assumed. No one brings with him into the world a genius of such quality that it would be capable of inventing articulate speech.

Degrees of speech among feeble-minded children.

(1) Those who neither speak nor comprehend language. There is found in these animal expression, that is instinctive, but it is in the form of reflex movements and inarticulate sounds.

(2) Those who do not speak, but have an idea of language, know when they are called, and know the names of a few objects or persons.

(3) Those who do not speak, but understand any simple sentence.

(4) Those who do not speak, but understand any ordinary language in the household. The defect here is somewhere in the nervous tract, between the centers of volitional impulse and the termination in the vocal apparatus.

(5) Those who utter a few words or sentences with little or no idea of language or the words or sentences used. The speech in these cases is imitative or parrot-like. The sounds transmitted do not reach the higher centers but pass to what may be called the subordinate region of the imitative faculty, where inspired by the reigning volition there, they emerge in the form of articulate sounds. The cohesion or association between sound and meaning is not established while the association between sound and articulation is.

(6) Those who speak a few words understanding their meaning and with a purpose in their use; these usually employ the gesture language as an aid to their imperfect speech.

(7) Those who utter brief sentences. These may be divided into two sub-classes: (a) Those who use such sentences in a natural way and in accord with the limited continuity of their thought; (b) Those who use brief sentences in a spasmodic and emotional way. In the development of speech, the usual order seems to be first imitative, then intelligent and emotional speech. There is, however, a peculiarity to be noted. Emotional speech becomes automatic, while intelligent speech has not the same tendency inasmuch as a constant self-determination is a necessity of the latter in view of varying circumstances. And so in aphasia, emotional speech, with its acquired automatism, is witnessed long after rational and voluntary speech has disappeared.

(8) Those who talk connectedly to the extent of their intelligence, in varying degrees, up to a fair command of language. In the last three classes there is more or less distinctness of utterance, depending first upon acuteness of observation and second upon coordination and flexibility of organs. In other words, upon conditions of sensory and motor nerves.

When speech is not established at the usual period, there is a want of flexibility in the organization later that renders its acquisition more difficult. And again, when in connection with defective coordination, speech at the outset has been imperfect and the habit of vicious utterance has become established, then later efforts to articulate properly fail of their purpose. The child can make all of the sounds of the language correctly perhaps, and even repeat sentences correctly, but falls back unconsciously into his habitual faulty utterance. The case of R. R. illustrates this well. When he first came under my observation he was said to have a language of his own, which no one could understand. It was soon discovered that he began all of his words with *n* or *m*. The child, a boy aged ten, had a large vocabulary of his own. After a year's training he had between two and three hundred words which he could speak correctly, but he had to be made to do so. Two years later he could speak all his words correctly if he would, but he has never of his own free will done so, and always when playing with the children uses his original way of beginning all of his words with *n* or *m*.*

With backward children defective hearing and seeing are large factors in defective speech. The case of A. C. well shows this. He thought it a fairy tale that birds sang. Though he talked fairly well, no one had discovered he did not hear high tones. He was taught to play a cornet and the difficulty was overcome, and he later heard the birds sing. Again, many a child is slow in receiving

*There are primitive tubes with languages in which all words begin with vowels. It would seem heredity must come in here.

sound. This makes them very backward in acquiring sounds. Such children do well if they are shown the movements of the vocal cords and are given exercises of singing the scale. A boy of six, though in kindergarten two years, had learned scarcely anything. He seldom spoke, did not attempt to join in singing, and never told of anything he had seen. His mother said "he had no memory." He was at a mental standstill. This child, by the use of a hand mirror, in six months learned to read remarkably well. This case shows how much can be overcome. His mind was awakened and he proved to have an excellent memory.

A teacher for the backward must possess a scientifically correct knowledge of the exact positions and actions of the vocal organs in speech. Without this it is impossible for the teacher to judge from the sounds made by the pupil of the precise condition of the various muscles used. And to be unable to do this prevents him from knowing whether the difficulty is a defect in the receiving of sounds, or a failure properly to direct the vocal organs. If primary teachers were trained so as to recognize causes of speech defects—this cannot be told in one lecture—they could accomplish results that would greatly reduce the number of dull scholars in the higher classes. Sight, too, must be trained, for these children see but they do not look.

Means of Developing Speech.—These obviously should be directed to the very point of imperfection of organism or fault of function, when this can be determined. The natural avenues to the brain and mind must be opened. Perceptions must be forced through obstructed channels. Conscious intelligence must be awakened. Volition must be stimulated and encouraged. The pupil must be made to comprehend language if possible, commands by gesture, the names of various objects; in other words, the necessary associations between sound and meaning must be established. At last, attention is directed to the vocal organs and exercises are directed to individualize and coordinate these. Then follow the imitation of sounds, simple musical exercises, elementary articulations, and the speaking of words, not especially those the most easily enunciated. Much individual work must be done. Again, there should be class work to get the benefit of the unconscious influence and force of associated action. If we have any method in teaching the backward to speak it should be first through rhythm—music, dancing and calisthenics seem to produce ideas; then follow sounds, words, and language—in the majority of cases.

The voice which sings emits vowels.* The teaching of music must be blended with that of speech, and first of voice. In singing, these vowels may be intoned, and after a while supported by consonants. This transformation is brought on insensibly in the course of the musical training and must be improved technically later. Music first pleases the feeble-minded child, attracts attention, and gives passive vibration to the muscles and nerves preparatory to and during exercises. Music is used to give perspicuity and continuity to the sense of hearing and to support the voice in learning to speak. It must be intermingled with most of the exercises and habits of the life of the child. It is a most useful agent, adapting itself to the teacher's deepest purposes.

The material of true speech has to be prepared out of the animal voice. The children low in the scale of intelligence have only a cry, a few not that, but these few arouse themselves at a musical sound. Out of 3,000 children only five did not have some appreciation of musical sounds. These cries and sounds move the diaphragmatic spring board on which they exercise their vocal organs in breathing and screaming—so getting chest gymnastics. These cries are voices. They are the early beginnings upon which we may be able to found the teaching of speech by altering the cry into a medium voice, supporting the voice on successive consonants, and so on, preparing the materials of true speech out of the animal voice. We must be sure that there are no physical or pathological defects. The moral incapacities of the child demand attention previous to entering into the training of speech. Good will on the part of pupil and teacher is also necessary as well as a good understanding between them. As language is the representation, by a combination of sounds and articulations, of all the human impressions and spontaneities, it is plain these children must find it the act most impossible and antipathetic to their nature, because it requires what they lack most, the correlation or synergy of several faculties with several organs.

Exaggerate accent and emphasis, with the exception of one single instance, viz., drop the accent when you want to command anything of which the child must make a choice of his own judgment. The gesture and the look must be as natural as the language.

The mechanical processes of speech are two. The first is mimicry for the formation of articulation; the other is borrowed from music for the training of the voice. At first the child is made to execute silently after his teacher the movements of the different parts employed in speaking. At a time when the lips are well closed, part them by thrusting out an emission of voice pronouncing *ma* or *pa*. If the child's lips are soft, then *ma* will come first; if firm and well shaped, *pa*. This rule governs all the labial, lingual, dental, or guttural syllables. We are governed at first by the structure of the organs, but after choosing the easiest to be pronounced first we soon disregard them. Difficulties are usually overcome by musical exercises. Group teaching is oftimes helpful, persevering by exacting voices out of mutism, long sounds out of short ones, series of emissions after single ones. The whole is done with the help of the piano or other instrument supporting well the voice. Afterwards imitation must be called in: group work here is good for the emission of syllables simple, double, or compound; once, twice, or more times, with or without music, with or without formal command. It is of some importance which syllables are first taught. *Ma* and *pa* come foremost, but if there are anomalies of the lips,—when the upper lip is thick and the lower thin and short,—"*va*" and "*fa*" are easiest. Some anomalies of structural relation concerning the teeth, tongue, and palate will offer other inducements to

*Scripture says: "The nervous impulses to the various portions of these muscles differ for the different vowels, with the result that the glottal lips contract differently for each typical vowel." The two essentials of the theory of Willis and Herman, namely, that the glottis limits puffs of greater or less sharpness and that the vowel tones are generally inharmonic to the glottal tone, can be considered as definitely established. The reason for the puff character of the glottal action has been found by Prof. Ewald (Strasburg) in the fact that the glottal lips are masses of muscles which yield by compression, and do not vibrate like membranes. That vowels are produced by membrane-like vibration of the larynx is a false theory.—(Scripture's "Voice," p. 7.)

avoid and to select different syllables to begin with. Rarely the tongue moves easier than the lips. If so, *"la"* and *"da"* are good for a start. When the organs are normal it is best to teach the syllables in the order in which they are emitted from the lip backward, from the seen to the unseen organs. Another rule is to commence the lesson with syllables beginning with a consonant, and to use those in which the vowel is enclosed between two consonants alternately with those in which two consonants precede the vowel, for fear the tongue should lapse into the habit of one of these pronunciations, and refuse to emit the others. The syllables beginning with a vowel come later yet, as it is a great deal easier to say *"pa"* than *"ap,"* the first utterance being supported by the lips, the second by nothing. In primary trials doubling a syllable renders their pronunciations easier and more attractive. Later, this might develop stuttering.

It is important to remember that speech is such a spontaneous faculty that it is not enough to teach the child to produce it. The chances are what the child learns to-day he will not show at once. He seemingly must digest it, but occasion will bring it out later,—or what the child learned and did not show in private teaching will appear when he shall take his part in the group, and *vice versa;* and what private or group emission of voice cannot bring out may flow from his lips without effort after some lazy looking on, and accidental hearing. We sow and nature fecundates. We must not expect to find the child using immediately the syllables or words which we have taught him with so much fatigue to ourselves; as if he had learned nothing he will continue to emit for his own use the bisyllabic repetitions whose grammar is music, *ahdada* in his joy; *ahnana* in his disappointment, ringing or nasal sounds which adapt themselves exactly to theories of philosophy, like the colors of a painter to a landscape. Our primary teaching must not touch this natural speech, taking care not to substitute Greek etymologies for those of passion, fearing to repress in the child its higher element, spontaneity. Rousseau says, "Everything is good as it comes from the hand of the Creator; everything degenerates in the hand of man." If anything is divine in speech it is not grammar; it is the bounteous fluency which flows like a stream from the soul.

The necessity of sight in the training of speech must be borne in mind. Sounds are taught by audition, but articulation is appreciated by the look. Sight is the sense function by which we receive, through light, the impression of objects standing or coming in its range. This is passive vision. Active vision is the faculty of the same sense, so very special and diversified that two painters never produce the same object in the same light. In feeble-minded children this has to be encountered in teaching speech. Even when they see quite accurately they seem to experience various difficulties in looking, in directing, or concentrating their willed regard in some direction or at some distance. Generally their look, when they have any, does not seem to go or stay where they wish. They see, but look badly or accidentally, and use their sight only for things they crave for. Some when asked to look at something, shut their eyes when trying to obey. In fact the sight is, of all our senses, the most intellectual and the one whose anomalies are the most varied and the most connected with the disorders of mentally defective and backward children.

The education of sight must be begun as soon as possible. The training of the eye presents more real obstacles than that of the ear, but one of the errors in handling these children is in trying to put the child through the eye stage before he has been through the ear stage; oftimes low-grade children will give heed to music, but give no heed to verbal sounds and speech. Words to them have no meaning. This would seem to indicate that inasmuch as language and speech are essentially a sensorihistorical function, and inasmuch as language was developed by attention being directed to the external world, and as language was the first result of a mental complex, made up of the identification of certain sounds and certain objects present in space, if we wish to develop in the child the attitude of attention toward words and their meaning, we must first begin at his stage of development, at his stage of mental sequence—musical sounds. The speech center and the leg, arm, and finger centers are adjacent to that of music. So to assist in developing speech, finger exercises on the piano and finger gymnastics are given to assist in developing the right coordinations and to develop the motor area of the brain.

The thought side must be given much prominence. Music as a factor in the education of all children, both normal and abnormal, should be given greater emphasis. I know a number of cases where music has been the basis of developing the mathematical concept in backward children. This dominant interest of such children is usually ignored, whereas it is of the greatest educational value. Children should be given more dancing. Dancing movements are a great help in developing other motor coordination,—speech in particular. Dr. Gulick's folk-lore dances would be most useful.

The class-room teacher in the schools should have a general knowledge of functional disturbances. Worry, embarrassment, excitement, etc., are immediate causes of speech defects. If the school is a place of nervous tension, if the child is constantly worried with adult forms and abstractions, ill fitted for its little mind, if it is asked to express its confused ideas under the eye of a critical teacher who perhaps considers her day's work to consist of five or six long hours of wearisome labor, we have conditions adapted for the production of functional speech disturbances, especially so since oral speech is not fixed till adolescence. The school should rather use its opportunities to cultivate good language by means of stories, conversation, and other oral exercises given sympathetically under the influence of a good model. The high percentage of stuttering during the first few years of school life is probably due to nervous tension and could be reduced considerably if the child in all cases had high-minded teachers who understood child nature, who knew how to subordinate deadening influences, and could make the life of the school so free and so unrestrained that fear, worry, and its train of evils were unknown in their presence; who could live with the child and organize its wealth of incoming information from its own point of view, and encourage it to react with oral expression as simple, as unaffected, as natural as the life of the child itself.

The training of speech should occupy an important place in the curriculum of schools, and especially in those for the backward and mentally defective. Not only in our schools, but in hospital and clinical work for children as well, speech-therapeutics should have a place. A care should be had

that this work has a scientific basis. As yet this country does not have much to offer for practical use. There are beginnings of such in Germany. Our medical schools should have chairs of preventive medicine which should deal with mental hygiene.

THE PREPARATION OF ROMANOWSKY STAINS.

By ROSCOE W. KING,

LAS ANIMAS, COLO.

LABORATORY U. S. NAVAL HOSPITAL.

By a peculiar conspiracy of circumstances the writer was led into an error in the article, "A Simple Method for Preparing a Useful Stain," contributed to the MEDICAL RECORD for July 17, 1909. Sodium sulphate is slightly soluble in absolute alcohol, and chiefly for this reason the partial neutralization of the sodium carbonate by means of the acid sodium sulphate is objectionable. The article above referred to was based on a series of experiments (see below) which have been carried out a great many times, using methylen blue, absolute and commercial alcohol derived from different sources. The results so far have been uniformly successful. In reporting these experiments it becomes necessary to describe the following products:

Blue by alcohol. This is prepared by dissolving 0.5 grams of acid sodium carbonate in one-hundred c.c. of distilled water and adding 1 gram of Grueb-ler's methylen blue. When solution is complete, transfer to a large (500 c.c.) porcelain evaporating dish and evaporate to dryness directly over the flame, using a wire gauze to distribute the heat. Boiling need not be avoided, but when about three-fourths the water has escaped the dish should occasionally be tilted and rotated to prevent spluttering. The time required for evaporating this solution should lay between one-half and one hour. When perfectly dry transfer the bulk of the stain to a 200 c.c. flask. The dish is then rinsed with four 25 c.c. portions of 95 per cent ethyl alcohol which is poured into the flask containing the dry stain. Agitate occasionally during an hour or so, and filter through a small white filter paper, previously moistened with ethyl alcohol, into an evaporating dish. Evaporate to dryness over the water bath or allow to evaporate spontaneously. The resulting blue stain is perfectly neutral. It is regarded as permanent since it has been kept for months in an open evaporating dish. It is advisable, however, to exclude moisture. Romanowsky staining fluids made from this blue have been used in this laboratory during the present year with uniformly good results.

Blue by ammonia: The exact method of preparation cannot be given in this paper. It is mentioned because experiments now making indicate that the use of ammonium hydroxide will afford a simpler means of obtaining the neutral blue. The blue used in experiment E was obtained by evaporating to dryness an ammonical solution of methylene blue. The formula, as well as the age of the solution being unknown. The experiment shows that excessive oxidation had occurred.

Experiment A. Dissolve 50 milligrams of blue by alcohol in 25 c.c. of C.P. methyl alcohol containing 40 mgms. of eosin. The resulting Romanowsky staining fluid is ready for immediate use. It does not require filtering. This fluid will, in every way, duplicate the results of the best of the so-called precipitate stains. Merck's Reagent Methyl Alcohol has of late been used. Twenty-five c.c. of this alcohol containing a few drops of phenolphthalein will show a faint pink color on adding 0.1 to 0.15 c.c. of decinormal sodium hydroxide.

Experiment B. Using the same amount of the blue and eosin as in A, but substituting commercial for the pure alcohol, it was found that the eosin overstained while the nuclei did not stain at all. On adding 3 mgms. (.75 c.c. of the decinormal solution) of NaOH, the resulting fluid was practically identical in staining properties with that obtained in A. Twenty-five c.c. of the alcohol used in this experiment required 1.5 c.c. of the decinormal NaOH solution to produce a pink color with phenolphthalein.

Experiment C. Made as B, except a different grade of commercial alcohol was used. The results were practically the same.

Experiment D. 10 c.c. of pure acetone + 15 c.c. of 95 per cent ethyl alcohol was used instead of the commercial methyl alcohol in B and C. The acetone was added for its fixing properties. The 25 c.c. of fluid required the addition of .4 c.c. of decinormal NaOH, after which the results were almost, if not quite, as good as when methyl alcohol is used. The keeping qualities of this solution are not known at present.

Experiment E. Made by substituting 50 mgms. of the blue by ammonia in B. On adding 1.5 c.c. of decinormal NaOH, the fluid gave beautiful results. The color of the nuclei, as well as the amount of alkali required indicated that the polychroming of the blue had been carried too far, and that for this reason the fluid would probably not keep so long or so well as those given above. Several experiments will be required to produce a perfectly satisfactory blue by means of ammonium hydroxide. These experiments are making in this laboratory. When it is remembered that Romanowsky staining fluids—no matter how prepared—are exceedingly sensitive to the presence of free acids or alkalis, it could not reasonably be expected that the commercial alcohols used in experiments B and C could be substituted for the pure alcohol used in A. The former show an equivalent acidity—to phenolphthalein—which is from ten to fifteen times as great as the latter. In using commercial alcohol for preparing the staining fluid under consideration proceed as follows: To 500 c.c. of the alcohol add 5 c.c. of a 1.2—1.25 per cent. aqueous NaOH solution. The alcohol so treated will still be decidedly acid to phenolphthalein. To 25 c.c. add 50 mgms. of the blue by alcohol and 40 mgms. of eosin. Have ready two or three fresh, thinly smeared blood films (on slides), each of which is divided into two or three sections by means of a wax pencil. Stain one section in the usual way. If the red cells are tinted with the blue add a drop of 3 per cent HCl alcohol; if the red cells are stained red while the nuclei are poorly stained, add a drop or two of the decinormal NaOH. After one or two trials a beautiful stain will result. Having kept an account of the number of drops of either—or both—the acid or alkali, and knowing that one drop of the acid is approximately equal to two drops of the alkali, the exact, or equivalent amount of either solution added is multiplied by 19; the product being the number of drops necessary to add to the remaining 475 c.c. of alcohol. Having in this way determined the amount of alkali required for 500 c.c. of the alcohol the experiment will not need to

be repeated so long as the same commercial alcohol is employed. The commercial alcohol treated in this way can be substituted for the pure one in experiment A. In preparing these commercial alcohols it should be remembered that the very best results may be obtained, and failure to do so will, in ninety-nine cases out of a hundred, be due to the presence of an excess of either the acid or alkali—the addition of a drop or two of either the one or the other, as may be indicated, will often make a perfectly satisfactory staining fluid from one that would otherwise be discarded as useless. This applies to solutions that have been kept for months as well as those that have been recently made.

Regarding the keeping qualities of the staining fluid, nothing need be said further than that the method outlined above is merely an improvement of the one suggested by the present writer some four years ago, since which time he has used it exclusively both in this country and in the tropics. It has also been used extensively by others, especially in the Naval Medical School, at Washington, D. C.*

To conclude: It might, and probably would, be advantageous to increase the blue in the above experiments to 60 mgms., with the view of obtaining a more durable staining fluid. It should be remembered, however, that the tendency of these solutions to overstain with eosin† after a longer or shorter time, is not due so much to the absence of the blue as to the presence of oxidation products of the alcohol, *i. e.*, aldehydes or acids. This is best overcome by adding a drop or so of decinormal NaOH to each 20 or 25 c.c. of the fluid. If the overstaining of the eosin is due to the presence of acids or aldehydes, the further adition of blue will be harmful and not helpful. For this reason it is never advisable to use more than 60 mgms.

For some unknown reason the alcohol used in experiment A is not especially well adapted for preparing Romanowsky staining solutions. The fluids so made are perfectly good, but they do not, apparently, keep so well as they should. In this respect it has but little or no advantage over a good water white commercial alcohol.

*Stitt's Bacteriology, Blood Work, and Animal Parasitology (Blackiston).

†If pure alcohol is used, which is, of course, always preferable, the staining fluid will, after two or three months, tend to overstain with the blue, due to the further oxidation of this pigment. The addition of one drop of 3 per cent. HCl alcohol to each 20 or 25 c.c. of the fluid will overcome this, and the staining properties will be exactly as good as a freshly made solution. In this way the staining fluid will give beautiful results after having been kept for many months at room temperature.

Backward Scholars.—Giacinto Fornaca discusses the education of backward children in public schools. There are two classes of deficients—those who are backward because they are not regular in attendance, this being the result of physical incapacity in some line, such as deafness or poor vision, and those that are deficient mentally. Some children do not advance because they are poorly nourished, others because they are growing and developing fast and have not strength enough to study well. Those who are deficient mentally may or may not show it in their looks. Some are apathetic, others too vivacious and irritable; both classes are unable to concentrate their attention on any subject. Some of these children show a loss of memory, while others have an excellent memory for music or mathematics. These children are well pleased with themselves, having no idea that they are acting foolishly: they may be emotional, sentimental, or affectionate. Some show a marked overactivity, and cannot refrain from slapping or pinching their fellow scholars. Important factors in the etiology of such conditions are alcohol, syphilis, tuberculosis, and toxic and infective conditions in the ancestors. This deficiency may be congenital or acquired, and epilepsy is frequent among these children, either petit or grand mal. The reflexes may be exaggerated, and there may be a spastic condition of the limbs, with spasmodic movements. As to the pathology of these conditions, sufficient examinations have not been made post-mortem. The treatment of these cases involves treatment of their eye condition, hearing, removal of adenoids, etc., in the first class of cases. The treatment of the mental defectives involves special schools, in which the children can be individualized, and the same teaching gone over day after day and hour after hour, interspersed with rhythmical exercises. They should be much in the open air, under the best possible hygienic conditions, and separated from their parents for the entire year, since when they leave school and return to their homes they rapidly go back to their original state.—*Gazzetta Medica di Roma.*

Thymus and Ovaries.—Francesco Valtorta reminds us that the thymus increases in size as long as the animal is growing, until sexual maturity is reached, and then involution goes on. If an animal be castrated the thymus increases in weight; if reproduction occurs it loses weight; the weight in castrated animals is only increased transitorily, later decreasing to normal size. The author has experimented on rabbits by removal of the ovaries, removal of both ovaries and thymus, removal of thymus and grafting it into same animal, removal of ovaries and grafting into same animal, removal of thymus and injection of extract of thymus, removal of both organs in same animal, action of extract of thymus and ovaries on the circulatory system, and action of same on organic metabolism. He gives his conclusions. In removal of the thymus in young animals the general development is affected and there are important alterations in the ovaries. Removal of the ovaries does not affect the thymus. Grafting the thymus does not affect the ovaries favorably. Injection of extract of thymus retards lesions of the ovaries; injection of ovarian extract produces no sensible effect. Removal of the thymus has much more effect in young animals than ovariotomy. The action of extract of thymus on the circulatory system results from the nucleoisotonics contained in the prepared juice. In the human body the thymus reacts by hypertrophy, the structure of the ovaries being profoundly altered, as happens in animals. Hypertrophy of the thymus coincides with hypertrophy of the lymphatic glands, and removal of the thymus in animals produces similar effects.—*Annali di Ostetricia e Ginecologia.*

The Legal Protection of the Child in the Struggle Against Alcoholism.—Hercod of Lausanne, in concluding his address on this subject before the International Temperance Congress in London, said: (1) The children of alcoholic parents, being minors, should be taken from them and confided to the care either of charitable institutions or placed in private families (abstainers, if possible). Unworthy parents should be made to contribute to their support, if possible. (2) The law should forbid even parents to give their children alcoholic drinks. In fixing the age the state of public opinion must be taken into account. Measures should be taken to make parents understand the reasons for such prohibition. (3) Minors up to the age of eighteen should be forbidden to enter a public house in order to drink unless accompanied by their parents. An exception may be possible in case of boarders, at meal times. (4) Children under fourteen years of age should not be allowed to enter a public house after seven in the evening, even if accompanied by their parents. (5) It should be prohibited to employ young women or girls under twenty, and youths under eighteen, as waiters, whether they belong to the publican's family or not.—*Medical Press and Circular.*

Hernia of the Fallopian Tube.—Giulio Cauli says that reported cases of hernia of the Fallopian tube are rare, and all seem to have happened under so different circumstances that no conclusions can be drawn from them as to the true cause of the condition. He reports a case observed by himself. The patient had undergone two pregnancies. She complained of pressure in the right inguinocrural region, lumbar pain, and a swelling in the right inguinal region. The menstrual pain was extreme, and there were marked nervous symptoms. At the operation the sac of the hernia was found full of limpid fluid and containing the Fallopian tube of the right side. The tubal serous membrane was continuous with the wall of the sac of the hernia, and the tube could be followed down to the cavity of the uterus. Operations relieved the patient of all her pains. The tube was liberated and returned to its normal place in the abdomen. Hernia was caused by the relaxation of the walls of the abdomen due to pregnancy and the increased intraabdominal pressure. The broad ligament was drawn down and formed a part of the hernial sac.—*Gazzetta Medica di Roma.*

MEDICAL ASPECTS OF ATHLETICISM.

AT the recent meeting of the British Medical Association a discussion was held on the medical aspects of athleticism in which many British authorities on the matter took part. The first speaker stated that with respect to mortality in connection with games among schoolboys and in colleges, he had collected information, that the death roll occurring from or during athletics during twenty years in a number of large schools with an attendance of over 6,500, and in a university with 2,000 undergraduates, was seven. As to injury to health as the result of athleticism opinions were somewhat divided. Clement Dukes, physician to one of the largest schools of England, holds that physical and mental education should coincide. According to him, mental education is pressed to its extreme limit of endurance in all cases and transgresses the limit in those deficient in stamina; this tendency must be counterbalanced by a deliberate method of physical education, whose aim should be the just equipoise of both disciplines. In discussing the baneful effects of athleticism Dukes defines it briefly and generally as the intemperance of genuine physical exercise and the various modes in which intemperance in exercise exhibits itself consist in excessive exercise, improper exercise or exercise unadapted to the age or strength of the individual, exercise taken at the wrong time of the day, such as immediately after a meal, and exercise unsuited to the season of the year. The points urged to avoid intemperance in exercise are: (1) Thorough physical examination; (2) individual apportionment of exercise consequent on the examination; (3) medical control over all severe exercise, so that even those who are physically fit shall submit themselves to appropriate training for the exertion. It is overexercise then that injures, and not exercise *per se*, which is beneficial and necessary.

As to the manner in which intemperance in exercise acts prejudicially upon the individual, the heart is the organ which most frequently suffers. But at the same time it is not quite clear that intemperance in physical exercises alone is ever wholly responsible for injuries to the heart. For instance, Houver, in Osler's "System of Medicine," states that "up to the present time there exists no absolute pathological and clinical proof of acute passive dilatation and death from excessive muscular exercise; although there are excellent physiological and clinical reasons for believing they occur, there always lurks the suspicion of other contributing factors in such cases, namely, a remnant of a former infection, congenital defects, or manner of life." Clifford Allbutt is of the opinion that the incidence of infectious disease is an element of the utmost importance. Among these infections he would place influenza in the front rank, but would also include severe colds, as a bad cold has quite a definite influence on the heart. Another speaker during this discussion, Sir James Barr, was altogether against any abolition of or even decrease of games at school or college, for he held that the more hazardous the game the better it was for the development of the character of the individual. He took the view that it might be well if youths entering for arduous contests had some medical supervision and advice by men who knew something of the nature and amount of work required in the contest. The question turned largely on the capacity for work of the heart and lungs, and as has been referred to before, the opinions of medical men vary enormously as to the amount of strain required to damage the heart.

The outcome of the discussion was that the evil effects of athleticism in Great Britain have been exaggerated and that outdoor sports and contests among youths and young men should be encouraged rather than hindred, always provided that the candidate has normal organs and is in good condition. There is probably no one who would seriously advance the proposition that games are not necessary to the health of schoolboys and young men. They make for character more than does mental toil. There would seem, however, to be no need that such games should involve excessive physical exertion. The tendency in this country was until recently, if it is not even yet, that games should be characterized by intemperate zeal. These remarks particularly apply to football. The season is short and the participants in college football are comparatively few, yet the list of fatalities and deaths has been greater in one season than the whole of the casualties and fatalities which have occurred in thirteen large English schools and in one university during a period of twenty years. This reads like intemperance in games indeed. Physical exercise taken properly is good for all, but abused is harmful to the individual and indirectly to the race. Under the present rules, however, the liability to casualties in a game of football is much less than it was, and it may be doubted whether it is necessary to reform the game much more. A hard "scrap" is to be expected, and it is only the opening for brutality on the part of some imperfectly civilized young biped that must be guarded against in this fine old game.

MALARIA AND ITS PREVENTION.

MALARIA is responsible directly and indirectly for more deaths and physical and mental breakdowns than is almost any other disease. The United States itself pays a very heavy death toll to malaria, and the number of deaths which occur in tropical

lands as a consequence of the malady is incalculable. To rid the world of malaria would be to rid it of one of its worst pestilences. It is stated by many authorities that the task of abolishing malaria is by no means beyond human means. But opinions are diverse as to the measures to be employed to bring about this result. The Government of India has decided to take vigorous steps for the prevention of malaria by ordering a conference to be held shortly, and Ronald Ross of Liverpool, the most enthusiastic supporter of the destruction of mosquitos as the only efficacious mode of driving away malaria, is greatly concerned lest the upholders of quinine prophylaxis should capture the conference and so force this method upon India. He expresses himself on the matter in the London *Times*, September 29, as follows, and his words in regard to malaria carry so great weight that they will be quoted in full.

"We are all agreed," he writes, "that for rural areas quinine prophylaxis, assisted if possible by screening is, broadly speaking, the most appropriate measure; but for towns and crowded areas opinion is divided, some advocating the same measure there also, but others preferring mosquito reduction. The latter measure has great and evident advantages. It tends to rid a town not only of malaria, but of other mosquito-borne diseases; and not only of these diseases, but of a persistent and ever-present pest which adds greatly to the discomfort of tropical life. It can be carried out by local authorities without troubling the public, a cardinal advantage in sanitary matters; and it helps to keep the whole town clean as well as healthy. On the other hand, quinine prophylaxis has comparatively many disadvantages. Merely to give or sell quinine at dispensaries and postoffices is not sufficient, because the poor cannot afford the time to be constantly attending such places for small doses of the drug. In my experience for the medicine to be really effective, either for general treatment or prevention, it must actually be distributed gratis or nearly so from house to house, and more than this, the occupants must be repeatedly urged to take it. We shall understand the difficulties here when we remember that it must be persevered with for long periods to be really useful, that it causes unpleasant effects, and that most of the patients in India are children. In fact, this process of distribution and persuasion requires a number of special dispensaries superintended by medical officers and necessitates a considerable amount of interference with the public if the matter is to be taken seriously. Moreover, quinine prophylaxis influences malaria only and does not relieve the public from the annoyance caused by mosquitos, but adds the unpleasant effects of the drug to their discomforts. Some writers claim that quinine prophylaxis is cheaper than mosquito reduction. This is probably true for rural areas, but untrue for crowded ones, where money spent for mosquito reduction is likely to give much greater benefit to the public than the same sum spent on quinine prophylaxis. Advocates of the latter measure always cite Italy as the great example of its success, but in Italy malaria is principally rural, and the conditions in India differ much from those in Italy. On the other hand, mosquito reduction has been the chief measure used in the Panama Canal Zone, Ismailia, and elsewhere, and is not nearly so expensive or difficult as its opponents pretend. I do not decry quinine prophylaxis, but the work should be obviously commenced in towns where a given expenditure is calculated to benefit the largest number of people."

F. A. Chester and C. C. Semple, respectively physician for the Santa Rita Mining and Exporting Company, Bluefields, Nicaraugua, and vice-president and general manager of the same, have contributed to *The Engineer* of October 2, an excellent article on malaria. In the course of their remarks they fall foul of a belief that is widely held that blacks are less subject to malarial infection than whites, and that natives are more or less immune to attacks. This is not in accordance with their observations. They find that natives living in the district and having lived therein all their lives, are just as subject to attacks as others, and that negroes not only are just as liable to attacks but usually furnish the most aggravating cases. White men, according to their experience, suffer the least, in regard to both frequency and intensity of the attacks. It is also generally believed that repeated infections gradually permit the tolerance of the poison or partial immunity, but according to the experience of those writers where quinine is not used prophylactically there is no such immunity. As to quinine prophylaxis there is some divergence of views with respect to the dose necessary to have the desired result. Chester and Semple state that the U. S. Army surgeons use 3 grains of quinine daily as a preventive of malaria in their work among laborers on the Isthmus. Many, however, think that a dose of 6 to 10 grains taken regularly every night is necessary to prevent a large number of infections, and have no faith in smaller doses. It would thus appear that quinine prophylaxis is somewhat uncertain, while there can be little doubt that the destruction of mosquitos is an effective measure. The difficulties in the way of mosquito destruction are sometimes very great, yet not so great, Ross says, as is generally supposed, nor is the expense prohibitive. Dr. A. H. Doty, the quarantine commissioner of New York, has recently shown what can be done in this direction in a comparatively open country and in the face of great natural obstacles, and Ross' contention receives further support by the success of the antimosquito campaign on the Isthmus of Panama. It would seem, therefore, that the war against malaria should be waged mainly on these lines. If there were no other argument in favor of it, it surely may be urged that the daily ingestion of from 3 to 10 grains of quinine, a drug which is poisonous to phagocytes as well as to malarial germs, should, if possible, be avoided.

Pulvis Acetanilidi Compositus.

Among the many important changes which have taken place in medicine during the past quarter of a century there has been little in the realm of pharmacy and medicinal therapeutics of greater influ-

ence on practice than the discovery of the coal tar antipyretics and analgesics. It was not long after their introduction, however, that a series of mishaps showed that these drugs were far from being unmixed blessings, and collapse, heart failure, and cyanosis occurred with sufficient frequency to warn the profession against their indiscriminate employment. To overcome the cardiac depressant action certain of the antipyretics were combined with various drugs, such as caffeine. One such combination of acetanilide, caffeine, and sodium bicarbonate is official in the United States Pharmacopeia under the name of pulvis acetanilidi compositus. The wisdom of an official endorsement of acetanilide has been questioned by many, and recently Worth Hale has strengthened this doubt by the results of an extensive series of animal experiments, the report of which appeared in Bulletin No. 53 of the Hygienic Laboratory of the United States Public Health and Marine-Hospital Service. The experiments were carried out on frogs, mice, and dogs. The drugs were administered in various amounts and by different methods and were given singly and in combination. The results were not uniform, though perhaps as nearly so as could reasonably be expected in experiments of such a character. The animals to which a mixture of caffeine and acetanilide were administered showed more profound and more rapid symptoms of intoxication than those which received a similar dose of acetanilide alone, and in some of the experiments even a half dose of acetanilide with an amount of caffeine in itself not toxic produced more profound symptoms than the whole dose of acetanilide given by itself. The caffeine seemed, therefore, to have an actual synergic action with the acetanilide. Sodium bicarbonate, however, had a distinct protective action against the acetanilide, though this was so slight that the alkali did less good than the caffeine did harm, as was shown by the greater toxicity of the mixture of the three drugs than of the acetanilide alone. The belief in the protective action of caffeine against acetanilide does not seem to have been based on any extensive scientific investigations, and it would appear, unless the results of Hale's experiments are disproved clinically, that the editors of the latest revision of the Pharmacopeia erred in admitting pulvis acetanilidi compositus.

Exophthalmos in Nephritis.

The facies of chronic nephritis is a subject which has been discussed and described in various articles and textbooks at greater or lesser length. Usually, however, such descriptions have been in some intangible way not quite satisfactory. The pasty, anemic complexion is fairly suggestive, and the puffiness of the eyelids, when it appears, is, of course, typical, but in many cases of interstitial nephritis it does not occur, and still not infrequently the diagnosis of nephritis is suggested by a glance at the face. It has long been a puzzling question to put the finger upon the particular characteristic in the face which makes the mind jump to the thought of nephritis. An article by Barker and Hanes, appearing in *The American Journal of the Medical Sciences* for October, 1909, may throw some light on this, and possibly tell us what we look for in diagnosing nephritis by the facies. They point out that one of the most common symptoms of chronic nephritis is exophthalmos. In fact, a careful examination of all the cases of nephritis admitted to Barker's service at the Johns Hopkins Hospital during the past few months demonstrated that exophthalmos was present to a greater or lesser degree in forty-eight per cent. of them. In some cases it was slight, in others very marked, the degree of bulging seeming to be intimately associated with the amount of uremic poisoning. All of the signs of exophthalmos, von Graefe's, Moebius', and Stellwag's, were present in a large proportion of the cases. Every patient showing albuminuric retinitis, and every one with fatal nephritis during the period of observation, had exophthalmos. These findings are of exceptional clinical interest as the occurrence of exophthalmos as a symptom of nephritis is not mentioned in the textbooks. If these findings of Barker and Hanes in their small series of cases are confirmed in greater numbers, there is a prospect of the establishment of a fact, not only of diagnostic, but also of prognostic, value. The proof of the existence of this symptom would furthermore demonstrate a degree of blindness existing in thousands of physicians who have studied earnestly the faces of hundreds of thousands of patients suffering from nephritis, but, failing to "look with the seeing eye," have not observed this striking symptom.

Dysentery Carriers.

During the past few years bacteriologists, sanitarians, pedagogues, justices, and newspaper reporters have all taken an active interest in a new danger with which the world is threatened, the dread of the germ carrier. This insidious and invisible lion in lamb's clothing first made its appearance in the form of the Klebs-Loeffler bacillus in normal throats. Following this "Typhoid Mary" left a wake of fever behind her as she moved from kitchen to kitchen, and competent observers now say that from four to twenty-five per cent of all typhoid convalescents go happily and unconcernedly through life scattering broadcast the most virulent of germs. Recently, too, similar healthy carriers of Asiatic cholera have been reported. To this deadly triumvirate must now be added still a fourth class of disease carrier, for in the *Deutsche medizinische Wochenschrift* for September 30, 1909, Heuser tells us that carriers of the dysentery bacillus occur. For a number of years, in an insane asylum in Germany, there have been annual outbreaks of dysentery among the patients, many of whom had been within the walls for many years. The epidemic this past summer was studied by Heuser, after it had subsided. The outbreak had been in a women's ward, and at the time the investigator arrived the patients had all recovered. A systematic search of the institution, however, revealed in the stools of three of the male patients, out of a total of six hundred, a few dysentery bacilli. Later a second epidemic broke out, apparently having its origin with a woman whose stools a few weeks earlier were reported as negative for the bacilli. The lesson which Heuser draws from his findings is that these three men were dysentery carriers and as such should be isolated and further that as a routine procedure in every case of diarrhea the stools should be examined for the dysentery bacillus, and if it is found the patient should at once be quarantined. It is to be hoped that a careful isolation of the three men in question will prevent future epidemics of dysentery in the women's wards of this particular German asylum.

News of the Week.

A Graduate Course in Experimental Medicine and Surgery at Columbia.—A graduate course consisting of thirty laboratory demonstrations will be given this year by the Departments of Physiology, Pharmacology, Surgery, and Bacteriology of the College of Physicians and Surgeons in this city. The instruction will be given by Dr. Haven Emerson, Prof. William R. Williams, Dr. J. W. Draper Maury, and Prof. Augustus Wadsworth. The sessions will be held from 3 to 5 P. M. on Tuesdays, Thursday, and Saturdays in November and December, 1909, and January, 1910. The course is intended to offer to physicians an opportunity to see demonstrated the more important and practical of the experiments of modern medical research and thus to come into critical touch with the newer laboratory methods as applied at the bedside in both medicine and surgery.

National Vital Statistics.—The first bulletin upon the annual death rate from the death registration areas of the country, as reported to the Secretary of the Department of Commerce and Labor, shows some comparative results in the death rate from various diseases in 1907 and 1908. Among the more important were the following with the rates per 100,000 of population:

	1908.	1907.
Tuberculosis (all forms)	173.9	183.6
Pneumonia (all forms)	136.0	161.2
Heart disease	133.3	141.7
Diarrhea and enteritis	116.0	116.7
Bright's disease	87.1	94.6
Cancer	74.3	73.1
Typhoid fever	25.3	30.3
Diphtheria and croup	22.3	24.3

The total number of deaths from all forms of tuberculosis returned for 1908 was 78,289, of which 67,376 were from tuberculosis of the lungs, 698 from tuberculosis of the larynx, 4,218 from tuberculous meningitis, 2,723 from abdominal tuberculosis, and the remainder from minor tuberculous diseases. The total number of deaths from tuberculosis returned for 1908 exceeded those of any previous year of registration, but the death rate per 100,000 for 1908 is considerably less than that for 1907. The death rate from tuberculosis showed a decline in all registration States except Colorado, Rhode Island, and Vermont.

Uncinariasis in Texas and Georgia.—The State Health Officer of Texas has issued a notice to the county and municipal authorities over the State calling attention to the prevalence of the hookworm and urging energetic action to stamp it out. A systematic examination of the students of the University of Georgia has demonstrated that over 30 per cent of them are suffering from uncinariasis. Many are from the wealthy families of the State. It is said that the class standing of the infected students is below the average of the college.

National Investigation of Pellagra.—The Acting Secretary of the Treasury announced recently that he had approved the appointment of a commission of officers of the Public Health and Marine Hospital Service to investigate pellagra. The inquiry will be carried on in Washington at the Hygienic Laboratory, and will be begun at the earliest time feasible. The department has acted because of the increasing number of cases in the United States, and because of the large number of letters asking for information which are coming in to Washington from Boards of Health in various States.

Anthrax in Louisiana.—The Louisiana State Board of Health reports an epidemic of anthrax in the neighborhood of Baton Rouge.

Examination for Medical Supervisor of the Indian Service.—The United States Civil Service Commission announces an examination on November 24, 1909, to secure eligibles from which to make certification to fill a vacancy in the position of medical supervisor in the Indian field service at $250 a month and expenses, and vacancies requiring similar qualifications as they may occur in that service, unless it shall be decided in the interests of the service to fill the vacancy by promotion, reinstatement, or transfer. Applicants must show in their applications that they have had at least three years' experience in medicine since graduation from a reputable medical college, and have had special training and experience in connection with tuberculosis and trachoma. Applicants must accompany their applications with certificates from reputable physicians showing that they are free from tuberculosis in any and every form. Age limit, 20 years or over on the date of the examination. This examination is open to all citizens of the United States who comply with the requirements. Applicants should at once apply either to the United States Civil Service Commission, Washington, D. C., for application Form 1312. No application will be accepted unless properly executed and filed with the Commission at Washington prior to the hour of closing business on November 13, 1909.

Committee on Obstetric Teaching.—The President of the American Gynecological Society has appointed a committee to report at the next annual meeting in Washington, on the present status of obstetrical teaching in Europe and America, and to recommend improvements in the scope and character of the teaching of obstetrics in America. The committee consists of the professors of obstetrics in Columbia University, University of Pennsylvania, Harvard, Jefferson Medical College, Johns Hopkins University, Cornell University, and the University of Chicago. Communications from anyone interested in the subject will be gladly received by the chairman of the committee, Dr. B. C. Hirst, 1821 Spruce street, Philadelphia, Pa.

For a Safe Fourth of July.—Cooperation of Governors of all States and Territories in a nation-wide campaign for the safe and sane celebration of Independence Day in every hamlet, town, and city throughout the country is the object of a movement now inaugurated. The plan contemplates the formation of a National Committee, the appointment as Honorary Chairman of President Taft in view of his indorsement of Washington's "accidentless Fourth," the appointment of the Governors of all States and Territories in the Union as members, and an active campaign by that committee all over the Nation for divorcing Independence Day from its annual toll of accidents.

Charitable Bequests.—By the will of the late Mr. Mitchel Valentine, after a few minor bequests have been given, the residue of the estate, valued at $2,000,000, is to be divided equally between the Presbyterian Hospital and Hahnemann Hospital of New York.

Tuberculosis Sanatorium in New Jersey.—A farm of 131 acres at Marshall's Corner, New Jer-

sey, has been purchased lately by Bishop McFaul of the Roman Catholic Church. On this site will be opened a sanatorium for the treatment of the tuberculous poor. Though the administration will be Catholic and the nurses nuns, the sanatorium will be open to patients of all creeds and all colors alike.

Pennsylvania State Tuberculosis Sanatorium.—A tract of 450 acres of land at Cresson, Pennsylvania, has been given by Mr. Andrew Carnegie for the Pennsylvania State Tuberculosis Sanatorium.

Additions to Insane Asylum.—Plans have been filed for an addition to the Oregon State Insane Asylum at Salem, Oregon. The new building will be for administrative purposes, housing of employees, and for an operating room. It will cost $100,000. Plans are also being made for the addition of two wings to the main hospital building at a cost of $125,000.

The Medical Society of the State of New York will hold its next annual meeting at Albany, January 30, February 1 and 2, 1910. The program committee will be glad to receive proffer of papers for this meeting. Letters should be addressed to Dr. L. H. Neuman, 194 State street, Albany, N. Y.

The Vermont State Medical Society, at its ninety-sixth annual meeting, held October 14, 1909, at White River Junction, elected the following officers for the coming year: *President,* Dr. W. L. Havens of Chester Depot; *Vice-President,* Dr. H. H. Ross of St. Johnsbury; *Secretary,* Dr. C. H. Beecher of Burlington; *Treasurer,* Dr. R. H. Stone of Burlington; *Auditor,* Dr. A. N. Norton. Next meeting will be held at St. Albans about the middle of October, 1910.

The Cheshire County (N. H.) Medical Society, at a meeting held at Keene, N. H., recently elected the following officers: *President,* Dr. A. W. Hopkins of West Swanzey; *Vice-President,* Dr. C. S. Walker of Keene; *Secretary and Treasurer,* Dr. E. A. Tracy of Keene; *Censors,* Dr. Ira J. Prouty of Keene, Dr. W. H. Aldrich of Marlboro, Dr. I. A. Loveland of Keene.

The Knox County (Me.) Medical Society was organized recently and the following officers were elected: *President,* Dr. M. P. Judkins of Rockland; *Vice-President,* Dr. W. F. Hart of Camden, and *Secretary,* Dr. A. W. Foss of Rockland.

The Thurbur Medical Association held its fifty-sixth annual meeting at Mulford, Mass., October 7, 1909, and elected the following officers: *President,* Dr. Solon Abbott of Franklin; *Vice-President,* Dr. George T. Little of North Uxbridge; *Secretary,* Dr. A. J. Gallison of Franklin; *Treasurer,* Dr. C. B. Hussey of Franklin; *Librarian,* Dr. J. M. French.

The Detroit Academy of Medicine held its fourteenth annual meeting October 12, 1909, and the following officers elected for the ensuing year: *President,* Dr. L. E. Maire; *Vice-President,* Homer E. Safford; *Secretary and Treasurer,* Guy L. Connor.

Brookline (Mass.) Medical Club.—At a regular meeting of this club, held October 13, the following officers were elected for the coming year: *President,* Dr. Henry V. McLaughlin; *Vice-President,* Dr. George W. Kaan; *Secretary and Treasurer,* Dr. Hale Powers.

Obituary Notes.—Dr. Maurice J. Stack of Washington died on October 17, aged 30 years. Dr. Stack was a graduate of the Georgetown University Medical School in 1876. For thirty years he had been assistant superintendent of the U. S. Government Hospital for the Insane at Washington, having refused the superintendency as he preferred the medical to the administrative work.

Dr. William H. Burroughs of Shannondale, Indiana, died at his home October 8, 1909, aged 60 years. He was a graduate of the Medical College of Indiana in 1887.

Dr. George Eastman Stubbs of Philadelphia died of apoplexy at Merion, Pa., on October 2, at the age of 70 years. He was a native of Maine, and he was graduated from Bowdoin College in 1861, and from the Harvard Medical School in 1863. He subsequently became an assistant surgeon in the United States Army and was honorably mustered out in 1866. He was brevetted captain of United States Volunteers in the same year for faithful and meritorious service. He was one of the founders of the Medico-Chirurgical College of Philadelphia, A. Tracy of Keene; *Censors,* Dr. Ira J. Prouty of years. He was at one time professor of anatomy and clinical surgery and of surgical pathology in the same institution. He was surgeon to Charity Hospital for a period of twenty years, and for a number of years was an officer of the Philadelphia Board of Health.

Dr. Solomon Apfel of Brooklyn, N. Y., died October 16, 1909, aged 65 years. His birthplace was Lemberg, Austria, from whose university he was a graduate. After serving in the Turkish army he became Mayor in one of the towns of his native country, then a member of the Austrian Chamber of Deputies for twenty years. For many years Dr. Apfel was a prominent figure in the medical profession of the East Side of New York, both as a physician and a writer on medical and sanitary matters.

Dr. William Joseph Dodd of Jersey City died October—in the house in which he had lived for over fifty years. He was 80 years of age. Dr. Dodd was graduated from the College of Physicians and Surgeons of New York City, and he served two years at Bellevue Hospital. He resigned from the staff and became one of the medical officers of the United States Army hospital steamer *Ben Deford* at the time of the Civil War. He practised medicine after returning to Jersey City, but retired many years ago.

Correspondence.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

OPENING OF THE SESSION—ARTIFICIAL FEEDING OF WOMEN PRISONERS—MEDICAL EXHIBITION—GIFT OF A HOSPITAL—OBITUARY.

London, October 8, 1909.

The new session was opened at the London schools in accordance with their announcements, which I indicated last week. Your space will only permit brief notes of the proceedings, confined mostly to the addresses to the new students. At the Middlesex Hospital Dr. Goodall told them that doctors, like poets, were born and not made, though they had to undergo a definite course of study at the cost of an indefinite sum of money. The minimum time allowed was now five years, but some had taken longer, and it was said that one gentleman had devoted twenty-two years to it without ever tiring of the amusement, ruining his health by overstudy, or satisfying the examiners—a story which elicited laughter and was followed by a more serious address on the value of experimental physics and the importance of recognizing the psychic factor as well as the physiological and pathological condition of every patient. The prizes were then distributed

by Mrs. Shackelton, and her husband made a speech in which he said that in his trip to the South Pole there were three doctors and surgeons on board and the expedition came through without any deaths. This caused a little laugh, on which the lieutenant added that the fact was due to the presence of the doctors. One man lost an eye out there and one of the leading oculists told him the operation had been necessary and was as well done as it would have been in a London hospital. This was satisfactory, seeing it was done on board ship and at a very low temperature. Another man lost a toe and now carries it about with him as a trophy in a bottle. Mr. Shackelton also mentioned the discovery of rotifers in a temperature of 50° to 60° below zero, which had been brought home and subjected to a heat of 230° Fahr. and were still alive, producing families, and having a good time. Another fact of interest to the profession was that they never got a cold in the Polar regions until they opened a bale of clothing which had been bottled up in England. Then they got colds, but those who went out into the cold quickly lost them, while those who had to remain in huts suffered for three or four days.

At Charing Cross the dean (Mr. Wallis) infused interest into his annual report by a vigorous attack on the regulations for graduation which go far to threaten the prosperity and even the existence of the London schools. The London University has always made rigid rules to increase the difficulties or severity of examinations. The consequence is that many of the most diligent students cannot obtain its degrees, and while great changes have been made with a view of extending its influence and opening education, the regulations respecting medical students continue to be a scandal.

Sir Clifford Allbutt afterwards gave an encouraging address to the students and strongly urged the importance of the study of anatomy.

Dr. Miers did not at St. Mary's Hospital pursue the subject which, as I reported last week, he put before another audience. He told the medical students that he could not approve the fashion of decrying the efforts of youth, for he considered that was the age of originality—the really productive period of a man's life. Anyone, he said, who took the trouble to search into the history of his own mental development, would find the germ of any original thought which had found expression in his mature life dated from boyhood or early manhood. So they would find that the later writings of great authors had been the development of ideas first formed in that period, just as the impression of books read in childhood were never effaced. The ideas of childhood came from without; the mental efforts of a later period came from within and were of the creative order; those which came still later were generally adopted from others. The students he was addressing were in the original, inventive, creative stage and should develop their own thoughts rather than adopt those of others. Much of our lives was spent in preparation for something else, often something never done. If they never undertook anything until completely prepared, they would accomplish little. He urged them to pursue their studies under the inspiration of a theory and the illumination of an idea. In all their work let them have a theory, let it be their own, and let them believe in it, test it by their own knowledge and experience, not other people's, even if later they had to reject it. Darwin formed the germ of his theory at the age of 23, Newton and Pasteur of theirs at about 24. Some would tell them not to theorize till they had more knowledge, but the pleasure of amassing facts was not the pleasure of real scientific work. After school days everything should be learned in the spirit of original research. So he counselled them in all their work to have a theory and stick to it as long as they could, to try to understand experiments before they were explained to them. Of course, he was not speaking of clinical practice, of which he knew nothing, but only of scientific studies.

Sir J. Tweedie having pointed out that, although the primary purpose of medicine was to relieve suffering and cure disease, it aspired to the still more important office of prevention and the removal of the causes of disease in the community as well as in the individual. From this he passed on to the importance of research—biological and pathological—and deprecated the failure to distinguish between the dissemination and the advance of knowledge. The crudest manifestation of the confusion of these was perhaps the belief, real or feigned, by some persons that inquisitorial experiments were performed in hospitals. Less crude was the notion that endowing sanatoria or special hospitals would solve the problem of the nature and origin of diseases and so hasten the discovery of cures. Logically the idea was false; economically it was wasteful. It was a misapprehension of the function of hospitals and the methods of scientific research. He would not discourage generous support to hospitals, which was needed continually. But he looked upon the endowment of research as the surest way of discovering the nature of diseases and the means of preventing them. Clinical observation threw but little light upon the intimate pathological processes. Supremely useful as hospitals were, it was true that most of the discoveries of scientific medicine were made outside them, and often apart altogether from clinical observation. As examples he named those relating to malaria, Malta fever, yellow fever, and in the surgical branch the aseptic system. They might be asked if experiments on living animals were justifiable. To answer they must not only be acquainted with the arguments on one side, but make themselves masters of both.

Dr. Rolleston, at St. George's, of which he is senior physician, took the opportunity of commemorating some of the distinguished men who in the school had advanced medical knowledge. Among these was Dr. John Snow, the anesthetist to the hospital, who made in 1854 the epoch-making discovery that cholera was conveyed by water. In that hospital hypodermic medication was first performed by Charles Hunter, at that time house surgeon. In 1894 or 1895 the first course of lectures on tropical diseases was given by Sir P. Manson. The pioneer, if not the founder, of the scientific study of tropical disease in India was Vandyke Carter, an old St. George's man.

The Socialists in the House of Commons have kept up all the week their daily questions as to the suffragettes who are being fed with the tube. Every day the Home Secretary has been able to report that their health is excellent. Yet the Socialist leader has suggested in questions that the method is an act of brutality beyond human endurance, that it is frequently followed by chronic pigmentary colitis, that asylum patients so treated as a rule die of the treatment, and other equally absurd statements. Another question was whether a memorial had been received signed by Sir V. Horsley and 116 medical men about the alleged dangers and inhumanity of the practice. Sir Victor is hardly the man to proclaim his utter ignorance of a medical question to the world, but if he has used such expressions as the Socialist leader would have us believe, what can one think? Is he so obsessed by the suffragettes as to have signed a paper without reading it? One hardly likes to think he has bid good-bye to either common sense or veracity.

Mr. Gladstone, Home Secretary, referred the memorial to the president of the Royal College of Physicians and in reply to his questioner triumphantly read the president's letter. Sir D. Powell did not agree with the memorialists, whose statements he described as inaccurate and greatly exaggerated. He said artificial feeding is largely employed among those who, from mental aberration, refuse to take nourishment otherwise, and also those who are physically unable to take it. He admitted that the method is not as free from discomfort as a reasonable diet taken naturally would be, but then added that patients have been so fed successfully for years. Of course, he assumed that it was carried out under medical control, which Mr. Gladstone assured the House was the case. In reply to further catechising, Mr. Gladstone has told the House of a case in which men prisoners have been similarly treated; that one of the women was at first violent and a gag was used to prevent her injuring herself. As to treating them as political offenders, he reminded his questioners that breaking windows, throwing missiles into meetings and crowded streets and otherwise endangering lives were offenses against the law entailing certain consequences. He added that the public had a right to protection, even policemen, prison officials, and cabinet ministers.

Last night a mass meeting of suffragettes was held in the Albert Hall to protest the "disgraceful coercion of women" and bid farewell to Mrs. Pankhurst, who is coming across to your side of the water to carry on her agitation. She, at least, made no attempt to minimize the offenses against law, but spoke of them as "rebellion" and declared repression will arouse women into more determined rebellion.

The fifth London Medical Exhibition was opened on

Monday and closes this evening. All kinds of instruments, foods, and other aids to the treatment of injuries and diseases were on show, and the exhibition seems to have been as successful as its predecessors.

Mr. and Mrs. Thomas Aitken have presented their former residence near Bury, with eight acres surrounding it, to the town for use as a hospital for consumptives. The monetary value of the gift is about £30,000.

Sir Thomas Smith, Bart, consulting surgeon to St. Bartholomew's Hospital, died on October 1 at the age of 76. He was a Bart's student and after minor offices was elected on the staff and rose steadily to the great position he long held as a favorite leading consultant. His Fellowship of the Royal College of Surgeons dates back to 1858, and he became vice-president. He served for a time as examiner in surgery to the sister college and as honorary secretary of the Medico-Chirurgical Society. He was many years surgeon extraordinary to Queen Victoria and has been sergeant surgeon to King Edward since his accession. He was made a Baronet in 1897 and a K.C.V.O. in 1901. He contributed freely to the Transactions of the Royal Medical and Chirurgical Society, to Holmes' System of Surgery, and the weekly medical journals. He acted as consulting surgeon to the Children's Hospital, the Alexandra Hospital, and other institutions.

Brig.-Surgeon William P. Ward, late of the Royal Artillery, died on September 29. He took the M.R.C.S. in 1846 and the L.S.A. the next year and at once entered the Army Medical Service. He served throughout the Crimean campaign, 1854-1855, and was in the battles of Alma, Balaclava, Inkerman, and the siege and fall of Sebastopol.

The death is also reported of Col. G. McB. Davis, late of the Indian Medical Service, at the age of 63. He entered the service in 1869, reached the rank of colonel in 1897, retired in 1902. He was in the Miranzi expedition, 1891, and the Hazira of the same year, the Waziristan, 1894-1895, and the Tirah, 1897-1898. He was in the action of Dargai and the capture of the Samphagha and Arhanga Passes and the Bara Valley, 1897, and was made a C.B. for his services. He also served in China in 1901-1902, and here, as in the former campaigns, was mentioned in dispatches.

Dr. William Rivers Pollock, obstetric physician to the Westminster Hospital and Queen Charlotte's Lying-in Hospital, died on the 5th inst., aged 50. He was a Cambridge graduate, 1888, and had been a St. George's student also. He was elected F.R.C.P. in 1901 and has served as examiner in midwifery and diseases of women and children at the college; was a Fellow of the Obstetric and other societies.

ACADEMY OF MEDICINE—PURIFICATION OF THE AIR—MENINGOCOCCEMIA—SOCIETY OF SURGERY—TREATMENT OF HYDATID CYSTS OF THE SPLEEN.

PARIS, October 10, 1909.

Prof. Charles Richet believes that an excellent method of removing from the air of a closed space the particles and microbic dust which it contains is to cause a viscous liquid or simple water to fall upon a ventilator in movement. This method differs completely from those usually employed in the purification of the air, for we usually content ourselves with introducing into a room air more or less purified. In this new method, on the contrary, it is the air of the room itself which is purified by the uninterrupted circulation of that air through the purification apparatus. The method is very simple; there is a ventilator moved by electricity which turns in a cylinder widely open above and below, to permit the free circulation of air through it. Above the cylinder is a reservoir of water, allowing the liquid to fall in drops upon the wings of the ventilator. By the rapid gyration of the wings the water is thrown in the form of spray against the walls of the cylinder; they fall again in rain and are received by a reservoir, in the center of which the entire apparatus is placed. The spray is condensed into drops which are filled with dust and microbes. When the concentrated residue is examined after evaporation, three liters of distilled water having circulated upon the ventilator for three hours, we find that it is considerable in amount, and contains a relatively large amount of solid materials. From the point of view of public and private hygiene, there is a great advantage in purifying the air, for, even if the microbes of the air are rarely pathogenic, they are so at times (bacilli of tuberculosis and grippe). If this apparatus does not destroy all the microbes, it certainly destroys a very large number of them.

Netter recently drew the attention of the academy to the fact that there may exist in the course of epidemics of cerebrospinal meningitis cases of generalized infection caused by the meningococcus without any symptoms of meningitis, and the existence of meningococcemia without meningitis should not be surprising, since we know that the meningococcus has been found many times in the blood, and even in the articulations and serous membranes. In connection with this subject Netter reports the case of a little girl six years of age, whose sister was attacked by cerebrospinal meningitis. The little patient had a severe febrile affection with articular pain, adynamia, purpura, buccal, and intestinal hemorrhages. The presence of the meningococcus was sought in the cerebrospinal fluid, but without result. At the same time there was agglutination of the meningococcus by the blood serum. On account of this observation two injections of antimeningococcic serum were made, and brought about a rapid cure. Netter then gave the results that he has obtained by serotherapy in 68 personal observations of cerebrospinal meningitis. Out of 68 cases there were 16 deaths, of which 8 either came in moribund, or death resulted from some other disease. Netter believes that antimeningococcic serotherapy is absolutely necessary, that it should be carried out with persistence, and that in some cases it is best to use as much as 300 cubic centimeters of the serum to obtain a cure.

At a meeting of the Surgical Society Morestin gave an interesting report of treatment of hydatid cysts of the spleen with reference to a case of Michon's. The patient was a man of 27 years of age, who became suddenly and severely ill, with fever, cough, and pain in the side, which caused a diagnosis of left sided pneumonia to be made. Some days after, following a severe attack of cough, the patient expectorated blood and débris of a hydatid membrane. The diagnosis of hydatid cyst of the lung, which had been emptied by way of the bronchial tubes, now become evident. Following this evacuation the general and local symptoms disappeared, but radiography showed below the diaphragm an abnormal shadow corresponding to the spleen, which seemed to show that there was a hydatid cyst of the spleen which had emptied into the bronchial tubes. Laparotomy performed by Michon showed, on the contrary, that the spleen was entirely free from all adhesion to the diaphragm or the neighboring organs. It contained a small, superficial hydatid cyst. This caused Michon to perform splenectomy. The patient was cured without any complications. Morestin believes that in this case there were two entirely distinct hydatid cysts, one in the spleen and the other in the lung, and that the last named was evacuated by the cough. He disapproves of the splenectomy performed by Michon. He should have preferred the enucleation of the cyst or the partial resection of the spleen, and in this case the spleen, an important organ, should not have been sacrificed. Quenu also believed that it was not necessary to have recourse to splenectomy in the treatment of hydatid cyst of the spleen except as a last resource, when other methods cannot be tried. If radiography allows of a positive diagnosis of an abnormal subdiaphragmatic mass at the same time it may lead us into serious errors. It was in such a manner that by means of radiography he had made a diagnosis of hydatid cyst of the spleen, but found himself in the presence of a subphrenic abscess.

Arrou insisted that the diagnosis between hydatid cyst of the spleen and hydronephrosis is difficult. In a case in which all the clinical symptoms made him think of hydronephrosis, Arrou called in George Luys, who, after a complete examination of the renal function and measuring the capacity of the pelvis by ureteral catheterism, stated that the kidney was not at fault. Operation showed that this diagnosis was well founded, the kidney was perfectly healthy; there was a cyst of the spleen. From the point of view of operation Arrou believes that the complete ablation of the spleen is not justifiable, but that it is best to practice partial resection. His patient was perfectly and completely cured.

Tuffier thinks also that conservation of the spleen in the course of the treatment of hydatid cysts of this organ is necessary in every possible case. Richard considers that when the spleen appears normal it is best to preserve this organ. He counsels the opening

of the cyst and reduction without drainage, or marsupialization, or, if necessary, the resection of the cyst. Splenectomy is not indicated except in case of multiple hydatid cysts or a single cyst which has destroyed the greater part of the splenic parenchyma.

SOCIETY OF GERMAN NEUROLOGISTS—NEW SIGN OF A NERVOUS HEART—TUMOR OF THE PINEAL BODY—TREATMENT OF PARALYTIC CLUB FOOT.

VIENNA, October 1, 1909.

ON September 17 and 18 there occurred in Vienna the third annual meeting of the Society of German Neurologists, under the chairmanship of Professors Erb and Obersteiner. There took part in the meeting some five hundred members, mostly from the German Empire. The general expression of opinion of the meeting was in favor of separating the neurological science from the psychiatric in the universities, and forming individual neurological clinics.

Docent Siegmund Erben of Vienna aroused much interest with a new diagnostic procedure. In cases of nervous heart if the body were placed in a certain position a sudden showing of the pulse occurred which lasted for some ten heart beats and then entirely disappeared. In myocardiac changes and in the beginning of aortic disease, on the other hand, this sudden transient bradycardia did not occur. Erben had used this method of examination for ten years, and it deserved the good will of the profession as a method of differential diagnosis. If before the examination one increased the cardiac activity by active bodily movements, the test appeared in even a more characteristic manner.

Professor von Frankl-Hochwart reported a tumor of the pineal body. This small appendix of the brain, in which Descartes at one time placed the seat of the soul, was considered for centuries to be quite purposeless. Only in the last few years has the significance of this organ been brought to light by a few investigators, among whom should be named Slawyk, Oesterreich, and Marburg. Frankl-Hochwart was the first to be able to make a diagnosis of a tumor of the pineal body during life. This was in the case of a four and a half years old boy who showed the developments characteristic of puberty of a boy of fifteen. The diagnosis was confirmed at autopsy. From this it appeared that the significance of this invisible organ in its relation to development was proved.

In closing the discussion on infantile paralysis, Lorenz spoke of the deformities of the feet resulting from this disease. The deformities, among which, owing to its frequency, club foot was of especial importance, were not produced by the severity of the paralysis itself, but by the asymmetry of it, in that one muscle group was more affected than another. The result was an injury to the so-called muscle antagonism. The less involved, stronger muscles pulled the foot towards their side, and the fixation in the pathological position by the body weight caused the development of the deformity in a maximal degree. The therapy of the paralytic deformities had made rapid strides in recent years, owing to the use of tendon transplantation, by which the loss of muscle antagonism was overcome. Lorenz well recognized the value of this operation, but was of the opinion that it was often performed unnecessarily. It often occurred, for example, that one muscle group was more strongly involved than its opponent, but still had some power left—was in fact not completely paralyzed, as the first examination of the extreme deformity would make it appear to be. We must not forget that by the development of the deformity both the degree of the paralysis and the injury to the antagonistic action was increased. The weaker muscles lying on the convexity of the deformity suffered, with the increase of the deformity, a passive stretching and permanent lengthening, lost thereby their power of action, and assumed, through prolonged lack of use, inactivity paralysis. The first step in the therapy of these conditions was to attempt to restore the power of these muscles before one took steps with operative procedures. A valuable means of reawakening the power in these apparently completely paralyzed muscles consisted in relieving their tension. This might be accomplished by reversing the deformity, by overcorrecting it as far as possible, by the Lorenz manual or instrumental means. This inverted deformity produced in this way should, after fixation in plaster, be maintained for several months in complete functional inactivity. After the expiration of this time one was often most pleasantly astonished to see to what an unexpected degree this apparently completely paralyzed muscle had recovered, so much so that very frequently operative procedures were unnecessary. Only when this relief of muscular tension had failed did Lorenz believe that tendon transplantation was indicated. For results from operation, then, he was very sanguine. The value of the operation could but increase if it was kept until the last resort.

RECIPROCITY IN REGISTRATION—PURE MILK—TORONTO GENERAL HOSPITAL—TYPHOID FEVER AT COBALT—SEWAGE DISPOSAL—SAND FILTRATION OF WATER SUPPLIES—GIFT OF A PASTEURIZING PLANT.

TORONTO, October 22, 1909.

A SUBJECT discussed at the recent meeting of the Canadian Medical Association, held in Winnipeg, was that of Dominion registration of physicians. It is obviously a question of the first importance, and members of the Canadian medical profession are beginning to appreciate this fact more fully. It appeared to be the general opinion of those at the meeting that a uniform standard of medical education should be adopted throughout Canada, so that a man who has taken the degree in one province might be able to practise in another province without being compelled to undergo the ordeal of examination. As a speaker aptly put the case, Canada should not be cramped by provincial boundaries. Of course, without a uniform system of medical education it would be impossible to introduce such a reform, but it is felt by the medical profession here as it is felt by a large proportion of practitioners in the United States, that a change in this direction would be beneficial to all concerned. It is believed that in a comparatively short period of time that five provinces of Canada will decide to adopt a system of uniform medical education and consequently of medical reciprocity.

A matter which is exercising the minds of medical practitioners in Canada in the same way as it is engaging the earnest attention of physicians and sanitarians in all parts of the world, is that of a pure milk supply, or rather of as pure a milk supply as it is possible to obtain. The problem of such a supply is not of the urgent moment here as it is in the crowded cities of Europe and Great Britain, but, nevertheless, in the Canadian cities it must not be neglected. In any event, the energetic medical men of Toronto are determined to take time by the forelock in this respect. In October last the Academy of Medicine, Toronto, appointed a milk commission and endeavored to get into touch with the dairymen of the city in order to formulate a working plan whereby the condition of the milk supplied to the city might be improved, and that the said dairymen might be induced to supply certified milk. The following were among the requirements adopted by the commission to guarantee milk: The herd to be tuberculin tested on admission, and twice yearly afterward, by a veterinary surgeon appointed by commission; he also to make monthly reports. Precise regulations as to cleaning of milk cans, milking sheds, milking utensils, and especially with regard to the personal cleanliness of the milkers themselves, and other technicalities. After having decided the requirements necessary to safeguard milk, the commission sent out a circular letter to about two hundred dairymen. A few considered the project, but the majority thought the precautions were unnecessary or, at any rate, too minute, and that the game was not worth the candle. Finally, three dairy firms took up the matter and are now producing certified milk to the satisfaction of the commission. The great obstacle to the production of certified milk on a large scale is the enhanced price of the product. Well-to-do people can afford, if they are so disposed, to pay a higher price for milk to protect the health of themselves, and especially of their families, but in many instances the poor cannot spare the money. Again, the community must be better educated with respect to the great part that unpolluted milk plays so far as public health is concerned. At the present time only a few understand or even partially comprehend the matter, and until this ignorance is conquered the sale of certified milk will be comparatively small.

The hospital question looms large in Toronto. The hospitals here, on the whole, are somewhat inadequate, and perhaps in some respects out of date. This is recognized by the medical profession, and soon two large hospitals will be in course of construction. The site for the new General Hospital is being rapidly cleared. It is on College street, and almost opposite the buildings of Toronto University. The site covers more than two acres,

and the building to be erected will be in keeping with the size and importance of the city, both as a commercial and educational center. In addition to the hospital proper, which will contain 400 beds or thereabouts, there will be laboratories for research, class rooms, and, in fact, all that goes to make up the equipment of a thoroughly up-to-date medical school. It is stated that the building with site will cost more than $2,000,000, and will be completed in about two years' time. Another large hospital is to be built. The Western Hospital has been for some time too small for the calls made upon it, and a new building is to be erected. This is to be built by piecemeal, so to speak, in blocks, closely adjacent to the site now occupied by the present building. Its capacity will be large, but it will be an inexpensive building, intended solely for use.

At the meeting of the Canadian Medical Association a paper was read by Dr. Bruce Smith on the hospitals of the country and their relationship to the people. In the discussion that followed the reading of this paper Dr. J. R. Jones of Winnipeg gave it as his opinion that the one thing to be avoided in Canadian hospitals was the pauperization of patients. Nothing should be tolerated which had in any way this effect. Indiscriminate charity was a most harmful influence in the community. The examples of England and Europe had only to be taken to show the truth of these remarks.

A serious epidemic of typhoid fever is in progress at Cobalt at the present time. Cobalt is the center of the silver mining district, and is situated in Northern Ontario, about 300 miles from Toronto. Typhoid fever has existed in Cobalt and neighborhood for some considerable time, but in August last it assumed the proportions of an epidemic. By the laws of Ontario when a township has a population of 5,000, it is no longer under the control of the Provincial Board of Health, but its local health authorities are responsible for its health and sanitary regulations. However, in the case of Cobalt and its neighboring mining camps the situation became so serious that the aid of the Provincial Board of Health was invoked, and towards the end of August Dr. Chas. Hodgetts, its secretary, and Dr. Bell, one of its inspectors, were sent from Toronto to Cobalt to render whatever assistance lay in their power. On arrival they found a most unsanitary state of affairs in the town and mining camps alike; no drainage or disposal of sewage, water derived from shallow wells, the water-closet system, when not lacking wholly, primitive in the extreme. Directions were given to close all the wells, and under their personal supervision the town was cleaned as efficiently as it could be in the existing circumstances. Recommendations were made to the mine owners to supply good drinking water in the mines and to provide in the mines the earth bucket system for the convenience and safety of the workers. The mine owners have erected for the use of their employees tent hospitals in the vicinity of the mines, and have also found a plentiful supply of efficient nurses. On August 9 last there were 56 patients suffering from typhoid fever in these hospitals, while in the town of Cobalt itself there were on the same date 41 sufferers from the disease. The disquieting feature of the situation is that there has been no decrease in the number of cases since the beginning of August. The death rate, however, has not been high, the disease being of a mild type. In Toronto there have been several cases of typhoid fever during the past few weeks. For a long time, indeed for the space of many years, it has been evident that the disposal of sewage in the city has not been calculated to promote the good health of the inhabitants. The greater part of the sewage is dumped into the harbor near the city, and where there is but little current of water. This has been going on for years, and, of course, with the rapid growth of population of Toronto the danger arising from this source has increased in proportion. The custom is not only dangerous, but extremely unpleasant to those living near the harbor and to the shipping. It is now proposed, and in fact some of the work with this end in view is going on, to carry the sewage by means of a large trunk sewer some miles from the harbor to the east of the city.

The water supply of Toronto, too, is undergoing overhauling. The supply is now obtained from or near the harbor, in which the sewage is placed, and although it is not suggested that the water supply is contaminated thereby, it will be altogether more satisfactory from a sanitary standpoint that the sewage should be disposed at so great a distance that there can be no fear of contaminating the water. The water supply is to be filtered, and it is stated that Mr. Alan Hazen of New York is to superintend the instalment of the slow sand filtration system. On the part of some of the citizens of Toronto there has been evidenced some dissatisfaction at this decision, they wishing to try the ozonization of the water by electricity. Lindsay, a small town in Ontario, has just had installed this system, which is said to have been employed with success in Wiesbaden and Paderhorn in Germany, in Nice, and at St. Maur, Paris, and in some other European towns, and to some extent in Philadelphia. The system is recommended by distinguished German scientists—van Ermengem and Erlwein; by De Frise, Roux, and others in France, and by Rideal in England. It appears, though, that a preliminary clarification by some kind of filtration is necessary before ozonization is performed. At the Fourteenth Congress of Hygiene and Demography, held in Berlin in 1907, a discussion on ozone purification of water was initiated by the French delegates and commented on by the *Lancet* thus: "It is sharply distinguished as being a sterilizing, and not a clarifying process, and its use presupposes that the water is practically free from suspended organic matter." There appears to be a great deal of confusion as to the cost, some stating that it is a very expensive process, while others declare that it is a remarkably cheap one. According to reports from authentic sources it is wonderfully effective as a sterilizing agent, and in all probability will be largely employed in the future for the purification of the water supplies of cities, but generally as an adjunct to filtration by other means.

Insanity is on the increase in Toronto and district. The Tuberculosis Institute at Montreal was opened by the King of England from West Dean Park, Chichester, by pressing a button connected by electricity with the Montreal Institute.

A milk pasteurizing plant has been given to the Hospital for Sick Children by Mr. J. Ross Robertson, who has on former occasions made very large gifts to the institution, and who built at his own expense the convalescent home in connection with the hospital on an island in the lake. Mr. Robertson took a party some few months ago to New York to inspect the milk supply of the city, and they were all favorably impressed with the working of Mr. Nathan Straus's charity. It is stated that since the installation in the Toronto hospital the health of the children has improved.

Progress of Medical Science.

Boston Medical and Surgical Journal, October 14, 1909.

Postoperative Acute Dilatation of the Stomach.—H. B. Smith gives a general description of this condition together with notes of seven cases and the results of certain animal experiments. He says that the condition is not rare but of comparatively frequent occurrence after operations under general anesthesia. It varies greatly in severity. Many cases recover spontaneously without the establishment of a positive diagnosis. Its occurrence cannot be foretold. It is probably the cause of some deaths. It is probably due to a primary gastroenteric paralysis, central or peripheral in origin or both. Trauma and anesthesia are probably the exciting agents of the paralysis. Mesenteric compression, if present, is a secondary factor. The most constant and characteristic symptom is the welling up of small quantities of bile-stained fluid at a time when post-anesthetic vomiting should have ceased. The most reliable diagnostic aid is the passage of the stomach tube. Prognosis is good if the condition is recognized early. Treatment should relieve spasm and evacuate both stomach and bowels. Operative measures are not indicated. Before we can rationally prevent it we must know more about its cause. Prophylaxis should be directed toward the lessening of operative trauma and anesthesia.

Cystoscopy in New Growths of the Urinary System.—Of 37 cases of bladder growths examined by L. Davis under the cystoscope 17 were pedunculated papillomata. Many of these were multiple and some were encrusted with urinary salts. Thirteen of the cases were primary vesical cancer, 2 of cancer of the bladder secondary to intestinal malignancy, 4 of cancer secondary to cancer of the prostate, and 1 of papillary cystoadenoma of the prostate. In examining a vesical tumor with the cystoscope, it is important to determine besides its form and probable character, details as to situation, size, number, and whether or not pedunculated papillomata are most apt to be found on the outer side of the ureteral orifices. One wants to know in removing such a growth how wide a sweep can be made about the pedicle without endangering the pedicle. It is hard to determine this fact at the time of operation owing to the bleeding. It is important to search thoroughly over the entire vesical wall, for when the bladder is opened

small tumors flatten out against the bladder wall and are hard to see. The author also considers new growths of the prostate and kidney and ureter. New growths in the kidney show hematuria at some stage in more than one-half the cases. Analysis of the urine from the two kidneys obtained by segregation of ureteral catheterization throw light on the diagnosis. Tumor cells, in the deposits, are rarely found. Tumors of the bladder may coexist with those of the kidney. A bladder tumor may simulate a renal tumor, especially if it is located close to the ureteral opening.

New York Medical Journal, October 16, 1909.

Epilepsy in Relation to Menstrual Periods.—A. Gordon presents a study of twenty-three cases, endeavoring to determine whether any irregularity of menstruation, or a diseased state of the ovaries, have any relation to the epileptic seizures. Only five women presented dysmenorrheic symptoms, but without apparent disease of the ovaries. A course of treatment by the gynecologist improved the condition, but did not totally remove it. As the epilepsy continued in spite of the improvement, the presumption was in favor of the fact that the irregularity and abnormality of the menstruation have not much to do with the seizures. This is only a presumption, but no certainty, as the five patients have not totally recovered from the dysmenorrhea. On the other hand, if we take into consideration the fact that the remaining eighteen patients did not present dysmenorrheic symptoms, it is evident that disturbed menstruation has no bearing upon the causation of epilepsy. He further states that their epilepsy consists only of one or two monthly attacks, but the latter are as typical as in any other form of epilepsy. There is loss of consciousness, frothing at the mouth, biting of the tongue, tonic followed by clonic convulsions, involuntary micturition, subsequent stupor. At no time during their illness had the patients seizures outside of the menstrual periods. As in any other variety of epilepsy, some of his patients began to present mental sluggishness and hebetude, and at the time they first came under my observation they presented the mental aptitude and general appearance frequently observed in many inveterate epileptics. The points emphasized by the author are: (1) The undeniable relation of epileptic seizures to menstruation. (2) Absolute freedom from attacks in the intervals between menstrual periods. (3) Apparently perfect integrity of the ovaries and still occurrence of epileptic fits immediately before or during menstruation. (4) The inability of controlling the fits with the usual bromide treatment. (5) The good and even excellent effect of thyroid extract. (6) The mode of administration of the latter, viz., thyroid extract between the menstrual periods and bromides without thyroid only a few days before menstruation.

Treatment of Acute Pneumonia in Infancy and Childhood.—W. L. Carr says that lobar pneumonia is a self-limited disease of short duration and it seldom demands more than nursing and care. Medicines are needed only when symptoms indicative of weakness or when complications arise, or when also restlessness and pain demand relief. Bronchopneumonia may be treated on the same plan, but it is a disease which usually even when acute, is associated with depressed vitality or infection and calls for the administration of alcohol and other stimulating agents. The main portion of the paper consists of the enumeration of the various measures and remedies for differing clinical conditions, and the details must be read by those interested. Concerning stimulants, the author says that he questions the direct action of strychnine, but believes in its good effects in cases of bronchopneumonia in which there is weakness of cardiac action or general failure of strength. Caffeine and camphor may serve as vasomotor stimulants, and digitalis may aid when the pulse is rapid, but for continued effect he believes that strychnine in doses of 1/600 to 1/150 of a grain, according to the patient's age, is the best circulatory tonic. In cases of severe depression the author combines it with caffeine hypodermically and when there is pulmonary congestion, edema, and a flagging of the right heart he uses nitroglycerin. Infants bear all of these drugs, but for them digitalis is unsatisfactory except in very small doses for a short time. It slows the heart action and increases the arterial pressure, and it is serviceable with older children with rapid and weak heart action. Its irritating effect on the stomach and intestine may limit its usefulness and require a change to strophanthus. He administers either drug in doses of one-half to two minims of the tincture every two hours for five or six doses and then as indicated.

The Prevalence of Venereal Disease Among Recently Arrived Immigrants.—A. L. Wolbarst considers this question with reference to intermarital infection. He refers to the man who is continent at home and who comes to this country alone to acquire sufficient funds to send for his wife and children. It is during this period that he is liable to acquire veneral disease, which, upon the arrival of his wife, he promptly communicates to her. The frequency of this occurrence is shown by figures given from one of the down-town, east side, New York City institutions; thus: (1) About one-third of 1 per cent. of all the male patients at the Beth Israel Hospital Dispensary, nearly all recently arrived immigrants, suffer from venereal disease, acquired after their arrival in this country. (2) Of 210 patients in whom the histories were carefully taken, 114 were single (54 per cent.) and ninety-six (46 per cent.) were married; of the married men, thirty-five (16 per cent.) were living with their wives in this city; sixty-one (30 per cent.) had wives in Europe ("celibate husbands"). (3) Most of the patients were infected after their first year in the United States; forty-four (21 per cent.) were infected during the second, third, and fourth years. (4) It thus appears that if these men were enabled to bring their wives to this country before the second year, the greatest danger from venereal infection might be avoided. Possibly the conditions are serious enough to warrant such assistance being rendered by organized forces having the welfare of immigrants at heart. (5) The number of wives thus infected unknowingly by their husbands must be very great, but there are no exact statistics that throw light on the subject. It would be interesting to have these figures. (6) The object of this paper is to call attention to the existing state of affairs—not to offer a remedy. There must be some means of remedying these conditions. They should be regarded as an economic measure, not only for the welfare of the immigrant but of his wife and the community in general.

Journal of the American Medical Association, October 16, 1909.

Antityphoid Inoculation.—W. J. Stone describes the blood changes during and following an attack of typhoid and says that the various antibacterial substances elaborated in the blood and tissues serve, according to most authorities, to protect the individual in most cases from subsequent attacks. The difficulty of diagnosis, however, between typhoid and paratyphoid affections, as well as mild types of meningitis and malarial and pneumonic infections, render the question of absolute immunity still somewhat uncertain. This immunity is due to the higher opsonic resistance after the disease and there are, besides opsonins, certain substances which are obtained by heating certain strains of typhoid bacilli which are more stable and even more active than opsonins. The methods of preparation of antityphoid vaccine are described, and those prepared from nonvirulent seem, according to later findings, fully as protective as those from virulent strains. The immunizing potency of these vaccines is impaired by age and affected also by extreme degrees of cold and heat. Room temperatures seem best for their preservation and it is safest not to use those more than three or four months old. Although a considerable immunity results from one inoculation of from 500,000 to 1,000,000 bacteria, it can be considerably augmented by a subsequent injection of 1,000,000 or 1,500,000 ten or fourteen days later. The injections are conveniently given at the insertion of the deltoid or in the abdominal wall, and should not penetrate the muscle. The reaction is slight and disappears within twenty-four hours. It is likely to be greatest after the second injection, but is seldom sufficient to keep a man from his work. The best time is in the late afternoon, so that rest can be secured early. The blood changes after inoculation consisting of increase of the agglutinins, bactericidins, bacteriolysins, opsonins, and stimulins are described. The duration of immunity produced has been estimated as from two to six years, but probably in many cases it endures for life, though this is not positively certain. The question whether the inoculation protects also against paratyphoid infection has not yet been fully settled. The good results of such inoculation in the British army are noticed. In one regiment no case of typhoid has occurred since the inoculation of the men in those who have received two doses, and the general incidence among all the inoculated men has been reduced to a small percentage of what it is among those not inoculated. Similar work has been done in the United States army since last December and is being continued, but the results are not yet published. Investigations have es-

tablished that about 4 per cent. of convalescent typhoid patients still have typhoid bacilli in their systems and are liable to disseminate the disease. The inoculation of antityphoid vaccine affords a more certain means of raising the bacterial resistance in such cases than any other known method of treatment. The inoculation involves no risk and is specially applicable to those that are exposed, such as nurses, physicians, etc. It is advisable, with our present knowledge, not to practise the method during the incubation stage of the disease to avoid the possibility of cumulative action, but in areas where the disorder is endemic or epidemic inoculations of antityphoid vaccine are indicated in individuals not in the prodromal or incubation stage.

The Combined Method of Infant Feeding.—H. I. Bowditch urges a thorough trial of the German, or caloric, and the American, or percentage, methods in combination and offers a plan by which this can be done. This plan depends on a table of caloric values for the different percentages of fats, sugar, and proteid used in infant feeding. These values are calculated for each gradual increase of strength in percentage and of quantity of food. These same values are placed side by side in columns and rows so that the columns represent values of different percentage ingredients of the same quantity, while the rows represent the same per cent. of ingredient of different quantities, for the former read up and down and the latter read laterally. The use of the table which accompanies his article is explained in detail. The fats differing in caloric values from the sugars or proteins are worked out by themselves and the sugars and proteins of similar energy power are estimated together.

The Sacroiliac Joint.—F. H. Albee carefully dissected fifty specimens and found in each instance a well-marked joint with synovial membrane and cavity, and strong, well-formed capsule, as constant in its size and relation as any other joint in the body. Before opening, many of the joints were injected with an aqueous solution of methylene blue, which colored the synovial membrane so that it could be seen to distend and retract all along the anterior-inferior aspect of the joint when motion was elicited. This latter could be brought about and measured in every specimen except one in which there had been an osteoarthritis and the anterior portion of the joint had been obliterated from this cause. Under favorable circumstances this joint will stand much abuse, as in case of a symphysiotomy, but it is liable to the affections of other joints and in case of infection the prognosis is often serious; first, because it is liable to be a metastasis from some other part, and, second, because of the danger of spontaneous drainage forward into the pelvis, owing to the thinness of the capsule anteriorly. It may also become relaxed and cause uncomfortable symptoms by too long recumbency, as well as trauma. His conclusions are given as follows: "1. The sacroiliac articulation has all the elements of a joint and therefore has a similar pathology. 2. It has motion and plays an important rôle in labor. 3. Its variation, according to individual, age, or sex, is very slight. 4. Its anatomy is such that drainage into the pelvis is apt to occur, and, therefore, in the event of infection, early posterior drainage is often indicated. 5. Its affections are, undoubtedly, the cause of many obscure and unexplained backaches and persistent sciaticas. 6. The important ligaments of this joint are so placed that the sacrum and the ilium swing open, in the event of a symphysiotomy, as described above, and little permanent damage results, even if the pubic separation has been great enough to rupture the unimportant anterior-inferior part of the capsule. 7. The relaxation of this articulation should be guarded against by support of the lumbar spine with pillows, etc., in cases of protracted postoperative convalescence. Undoubtedly, many can recall instances of nature's warning, in the form of a convalescent's backache, which the nurse so readily relieved by merely placing a pillow under the lumbar spine."

Persistent Thoracic Sinus.—C. N. Dowd has performed the operation of lung decortication connected with thoracoplasty in fifteen cases in children and describes the condition and changes calling for the treatment, his method of operation and the means of avoiding its necessity. In his patients ether was used, the patient lying on the sound side. The operation proceeded as follows: "'Orientation' incision was made about the sinus opening with resection of 3 or 4 inches of the rib above and the one below it. The incision was then carried upward in anterior axillary line to the third rib. The ribs were divided and suitable portions removed, usually one-half inch from the second or third, 4 to 6 inches from the tenth, and corresponding pieces from the intermediate ones. Sometimes less was taken away. With suitable retraction an excellent view of the sinus is thus obtained. A longitudinal incision is then made through the upper part of the sinus wall until the lung is reached. At this stage of the procedure the patient is allowed so nearly to emerge from the anesthesia that he will cough, when the lung usually bulges into the incision. The membrane is then separated from its surface over as large an area as is practicable and removed. In most of these cases a strip 2 or 3 inches long and from 1 to 2½ inches wide has been removed. This about represents the pulmonary portion of the sinus lining. The chest wall was nearly brought together by strong sutures and a drain or suction tube inserted in the unclosed part." The amount of chest wall removed varied according to the case and according to the likelihood of gaining lung expansion. In every case persistent and continued blowing on James's (or Wolff's) bottle has been used, and he thinks the expansive power accompanying this method is very great. The results are very encouraging, twelve of the fifteen being perfectly well, with varying degrees of chest expansion and capacity, and without lateral curvature of the spine. One patient is still in the hospital, one died of tuberculosis, and one was removed while doing reasonably well two days after the operation, and died a few days later in unsanitary tenement surroundings. Prompt relief of pyothorax before lung compression takes place, is the best method of avoiding these sinuses. The author's deductions from this group of cases so far as he thinks they can be justified are: "1. Persistent thoracic sinus can be cured by decortication of the lung and resection of the chest wall in 80 to 90 per cent. of the cases. 2. After operation the patient will not have lateral curvature of the spine. 3. The lung capacity on the affected side will remain much diminished. 4. Nearly all the patients are in good health and are not materially inconvenienced by this restricted lung capacity. 5. The mortality from the operation is probably more than 5 per cent. and less than 10 per cent."

Odors and Digestion.—G. M. Niles says the digestion may be influenced by the olfactories in several ways—directly, reflexly through idiosyncrasies, or by some complex psychic process hard to analyze. That appetizing odors make the mouth water is a common experience, and Pawlow has shown that the gastric juices are also susceptible and appetizing odors can create that gnawing sensation in the stomach that only an abundant flow of the digestive juices can produce. On the other hand, there is no factor that can exercise a more malign influence on the appetite and digestion than repulsive smells, as everyone has experienced. Even after digestion has normally begun, a disagreeable odor may destroy its progress, inhibiting the secretion of gastric juice, and causing stagnation, fermentation, and irritant decomposition products. Niles notes the effects of certain odors on particular individuals and gives instances where a surfeit of specially odorous food has impaired digestion long afterward when that food was present. These instances are real idiosyncrasies and not manifestations of prejudice or pretense. Odors may even cause death, a fact which was known even in ancient times when it was used as a punishment to chain a man to a dead body till death relieved him. Agreeable odors, on the other hand, may exercise a highly beneficial effect on digestion, a fact which is utilized among orientals, and he thinks that this field can well be studied and cultivated by gastroenterologists among ourselves.

The Lancet, October 9, 1909.

Hirschberg's Febrile Infection.—A case of this nature is reported by C. Stoncipher. Hirschberg mentions the following as features of the disease: (1) failure of the blood to agglutinate with the usual organisms, such as *B typhosus, B paratyphous,* and *B coli;* (2) absences of relapses, hemorrhages, phlebitis, rose spots, splenic enlargement, mortality, and of lengthy period of incubation and prodromes; (3) presence of constipation except when the patient is fed on a raw milk diet, and (4) normal blood picture as regards hemoglobin, erythrocytes, and leucocytes. Stoncipher's patient, a single woman of 22 years, followed the course outlined, the febrile course, never high, running 17 days and then falling to normal.

The Clinical Significance of Albuminuria.—N. Tirard says that the chief difficulty connected with cases of albuminuria is not concerned with the detection of minute traces, but with the significance of the albuminuria. The quantity of albumin is often an insignificant factor, but other factors, such as the quantity of urine excreted in 24 hours, the color, specific gravity, presence of other constituents must be taken into the account. General symptoms may be present or absent. Mere febrile albuminuria never appears to be associated with any grave interference with the renal function. Similarly albuminuria rarely causes any anxiety in patients who are suffering from disease involving retardation of the blood flow in the renal capillaries. The problem is a more difficult one in cases of albuminuria in connection with obvious heart lesions. Here the quality of the pulse and the presence even of the slightest amount of edema must be taken into account. Some of the most serious forms of albuminuria may be those in which the detection of the condition may be at times extremely difficult. Attention must also be paid to the time of voiding the specimen in relation to the ingestion of liquids, the permanent nature of a high or low specific gravity and the possibility of some disturbing factor, such as a diarrhea, recent violent exercise with profuse perspiration, and even excessive nervousness at the mere facts of examination. The presence of casts may be of assistance provided that too much importance is not attached to a few hyaline casts. Such casts are likely to be present whenever albumin is found in acid urine. Their absence can hardly be looked upon as a proof of the nonexistence of possibly serious structural renal changes. In those who have been long addicted to athletics, albuminuria is often found, with or without cardiac abnormalities. Here the question must be decided between cause and effect on one hand and the reference of both to a common cause on the other. Indications of arterial rigidity are not much value in the separation of functional from organic forms of albuminuria. The author summarizes his conclusions by saying that a large amount of albumin without blood or pus may generally be taken to indicate chronic tubal nephritis, and this can be confirmed by a high specific gravity, by microscopical examination, and by the appearance of the patient. A very small trace in an elderly or middle-aged man will probably indicate chronic interstitial nephritis; confirmatory evidence can be found in the aspect, the history, the pulse tension and tracing, the outward displacement of the cardiac impulse, the accentuation of the systolic apical sound, and the accentuation and reduplication of the second sound at the base of the heart. These indications may be further supported in some cases by the pale color and low specific gravity of the urine; less frequently information may be gathered from the presence of casts and from their predominant characteristics. The absence of casts is not, however, to be regarded as an indication that the case is not one of chronic interstitial nephritis. In a young man a mere trace of albumin may be the only evidence of a functional albuminuria, and the diagnosis must then rest upon negative evidence to a large extent, one of the most important factors being the relatively high specific gravity, unless this has been influenced by nervousness or by the recent consumption of a large quantity of liquid. With the same limitations the deep color of the urine will lend confirmatory evidence.

Investigations into the Etiology of Erysipelas and Allied Infections.—P. N. Panton and J. E. Adams describe their experiments, presenting much of their net results in tabulated form. They define erysipelas as an acute inflammation of the epidermis due to the presence of one of the organisms of the streptococcus class, of which the *S. pyogenes* is the most frequent example. Cellulitis appears to be a strictly comparable inflammation of the cellular tissues, and when the inflammatory process involves both the epidermis and the cellular tissues, the condition of cellulocutaneous erysipelas results. Acute lymphangitis would seem to be a less virulent infection due, as a rule, to organisms of the staphylococcus class with a greater tendency to spread, as its name implies, by the lymphatic system. Erysipelas is not in the true sense of the term a specific disease, since it may be produced by a variety of organisms and these organisms are capable of producing other diseases in other parts of the body.

Syphilitic Reinfection Nine Years After, with Some Remarks on Syphilitic Immunity.—In 1897 a gentleman consulted H. Dardenne for a chancre, which was cured in the usual way in three weeks. Secondary symptoms came on, but the disease was cured in a few months. Nine years later the patient appeared with another chancre and the usual symptoms appeared in due time. Under the same treatment the disease was cured. According to the great majority of authorities reinfection with syphilitic virus is possible. Several definite cases are referred to by Dardenne. We must be careful, he says, not to confound a true syphilitic reinfection with what Fournier calls "late secondaries," such as erosions of the penis, the vulva, and the lips. A recurring roseola may also be a source of error. One attack of syphilis does not confer immunity for the rest of the patient's life. It is believed that the chief feature of immunity is its coexistence with the presence of an active virus in the organism which may confer a refractory state to the skin and mucous membranes to the attack of the external treponemes. This skin and mucous membrane immunity, however, may not be general and absolute. The majority of syphilitics react in a specific way to the virus and this in proportion to the amount of virus which they have ingeniously injected in subcutaneous pouches. Fournier advises that the treatment be divided as follows: 1st. Immediately after infection, a course of mercurials lasting two years, and this whether the patient is troubled with reminders or not; 2d, a second course lasting the whole of the fifth year, and 3d, another course or mercury lasting part of the seventh and eighth year. We know that general paralysis, the most dreaded of the late syphilitic manifestations because it is incurable, is most common between the seventh and twelfth years after infection. Would it not be possible to forestall this by the plan of treatment indicated? Immunity in syphilis is only a relative signification. It does not in the least imply an absolute cure.

British Medical Journal, October 9, 1909.

The Cause of Dysmenorrhea.—F. C. McCombie relates the case of a woman with dysmenorrhea before her marriage. The cervix was dilated and kept open by bougies, affording her great relief. She gave birth to two healthy children. More recently, however, she complained of great pain during the third day of a regular menstrual period. She had passed some clots, and an examination was made. In the cervical canal there was found tightly gripped a mass of clot and membrane which was removed with great difficulty. There was distinct spasm of the internal os which was with great difficulty overcome. The discharge continued for several days, with pain coming on regularly at a fixed hour every day, and often requiring morphine for its control. She was examined several times during the attacks of pain, and while the cervical canal remained patent one could distinctly feel a constricting band at the upper end of it, almost impossible to dilate with the finger so long as the pain was present. Both before and after the spasms it was not noticeable. The patient herself remarked that a few hours before the pain came on the discharge increased in amount, but was diminished while the pain persisted, and again increased as the pain passed off.

Alcohol in Relation to Multiple Neuritis.—J. S. Bury refers to the finding of arsenic in beer, which was the reputed cause of multiple neuritis. This brings up the question as to whether the alcohol in beer may ever cause the same lesion. The author is inclined to think, on the basis of collective investigation, that this is the case. Beer taken by those who have had the disease has been carefully analyzed and found free from arsenic. It is open to any one to say that it is not the ethylic alcohol, but some accidental impurity which is responsible for the neuritis; but until this toxic agent, which is certainly not arsenic, is discovered it is impossible to resist the conviction that alcohol, whether in the form of beer, wine, or spirits, is a common cause of multiple neuritis. This statement does not imply, however, that the disease occurs frequently in alcoholic subjects, nor that the disease is the direct result of alcohol. Other factors may play a contributory part. The action of alcohol may be an indirect one in the production not only of neuritis, but of hepatic cirrhosis, and of changes in the heart muscles. It is a reasonable assumption that the lowering of tissue resistance by alcohol permits the successful attack of toxins derived from microorganisms or from the changes associated with chronic inflammation upon the nerves, liver, heart, or other structures. Whether the neuritis is a direct or indirect result of the poison, there is ample evidence to justify the view that well-marked cases of multiple neuritis (although not common) are produced more frequently by alcohol than by other poisons.

Paroxysmal Tachycardia Disappearing After an Attack of Herpes Zoster.—A. C. Turner's patient was a girl of 15 years who was having attacks of tachycardia during which the pulse reached 160. The first attack came on in the night, soon after she had taken a cup of strong tea. Thereafter the attacks recurred about every two months. They were terminated by vomiting of a small

quantity of sour fluid. There was no evidence of cardiac enlargement and no murmurs. No drugs seemed to relieve her, nor did pressure on the vagus. On October 10, 1906, she had severe pain in the left wrist, which continued the next day, when it affected the inner side of the left arm, the front of the left shoulder, and the back. The next day a rash appeared about the left shoulder and arm, the left ear became painful, and the right wrist also. In fact, she had a typical herpes zoster affecting the area of the second left dorsal segment, viz., the under and inner part of the left arm, the left breast in the region of the axillary fold, and the upper part of the left scapula. The rash ran the usual course, and since that time the cardiac attacks have not returned.

Berliner klinische Wochenschrift, September 27, 1909.

Cleft Palate Operation.—Helbing reports on the result of 53 operations for cleft palate. He used in every case the classical method of von Langenbeck. He differed from Langenbeck, however, in advocating early operation: as soon after three months of age as possible. In his 53 cases he had no deaths. Of 5 infants in the first six months of life in 4 the first operation was successful, in 1 it failed. Of 7 between six and twelve months, 5 succeeded, 2 failed. Between one and three years were 12 cases. Of these, 7 were cured in the first operation; in 4 a small fistula remained, which was closed later with ease; 1 case was a failure. Between four and six years, of 18 cases 12 healed at once, 3 after a second operation, 2 left temporary fistulæ, and 1 failed. Between seven and twenty-eight years there were 11, with 8 first operation recoveries, 1 second operation, and 2 fistulæ. Of the total 53 cases 40 healed after first or second operations, 8 were cured after a fistula, and in 5 the operation was not a success. The advantages of the earlier operation are that the operation is no more difficult in the very young if one uses smaller instruments; the prospect of the stitches holding are as great, if not greater. The danger to the child is equally slight, and, considering the high mortality among children with this deformity during the first year, the early operation is a much safer procedure than the late; and, finally, the functional results of the early operation are much greater, the voice often becoming quite normal.

Münchener medizinische Wochenschrift, September 28, 1909.

The Rôle of Albumen in Infant Feeding.—Grossen gives a historical review of the work and opinions on the differences between the casein of woman's and cow's milk. Heubner showed that woman's milk was much poorer than cow's milk in nitrogen, and that at that a considerable proportion was due not to proteins, but other nitrogenous material. To maintain life, 4 per cent. of the total calorie intake must be protein; to insure growth, 7-8 per cent.; in ill children somewhat more is needed. Biedert called attention to the difference in the curds, and considered the curds in the stools to be casein. The reasons for believing this and the facts which overthrew it are given. The work of Finkelstein and Meyer showed that cow's casein in itself was not injurious to infants. The theory was raised that the indigestibility of cow's milk was due to the small amount of lactalbumen contained therein. This was disproved by Meyer and the author. Neither chemical nor metabolic researches show any reason for the injurious qualities of cow's milk. Serological investigations have been made. Wassermann showed that injection of a foreign milk into an animal produced a precipitin against that milk to appear in the blood serum. Schlossmann demonstrated that an injection of cow's blood serum into an infant on a cow's milk diet caused no symptoms, whereas injected into breast-fed children it produced a violent febrile reaction. Moro observed that artificially nourished infants had a digestive leucocytosis, but breast-fed ones did not. The author does not believe that the indigestibility of the cow's milk is dependent upon a difference of the casein *per se*.

Polyneuritis Syphilitica.—Steinert summarizes an article running through two numbers, as follows: There is such a condition as polyneuritis syphilitica. It begins in the secondary stage of the disease, most frequently in the early secondary stage. The majority of the cases have simultaneously skin or mucous membrane symptoms. The occurrence of a syphilitic polyneuritis has not been known in the tertiary stage or in the parasyphilitic diseases. The fear of mistaking the condition for a mercurial polyneuritis is unfounded. Though polyneuritis often comes on during or following a mercury treatment it is not a part of mercurialism. The clinical picture in a majority of cases is of a symmetrical polyneuritis. It is possible that the upper extremities are involved somewhat more frequently than is usual in polyneuritis. The comparative frequency of the pseudotabetic type is noticeable. The prognosis is not absolutely hopeful. There are cases of a malignant type, with a fatal course. As a rule, however, recovery occurs. The pathological picture coincides exactly with other forms is usual in polyneuritis. The comparative frequency of treated energetically with mercury. It has not been shown that such a treatment can do harm.

Deutsche medizinische Wochenschrift, September 23, 1909.

The Previous Efforts to Cultivate Spirochæte Pallida.—Schereschewsky discusses generally the efforts to date to grow the *Spirochæte pallida* and to make use of it in inoculation experiments, and he concludes that it is possible to cultivate from syphilitic material spirochete which it is not possible to differentiate in any way microscopically from the true *Spirochæte pallida*. Neither by agglutination, precipitation, or complement binding reactions has it been possible to prove any specific connection between the cultivated spirochete and the serum of syphilitic patients. Efforts to produce a cutaneous reaction with the cultures were fruitless. The cultivated spirochete were not pathogenic for animals.

The Treatment of Tabetic Ataxia.—Herzog reports a series of cases of tabes dorsalis treated by local faradization of the bladder. His first case was a man who had been under treatment for some time by various means. Owing to incontinence of urine, faradization of the bladder was used. A flat electrode was placed over the abdomen, a urethral electrode inserted into the bladder, and a painful current passed for three minutes. Twenty treatments were used. The result was not only improvement in the urination, but in the walking also. The improvement was so marked that the patient, an army officer, was able to return to his duties. In this and three other patients results were obtained twice satisfactory, once outspoken, and once very marked. The author appreciates the rôle of psychic influences in tabes. It is possible that the improvement in the cystitis is the cause of the improvement, but in two cases there was no cystitis. He believes that the irritation of the sensory nerves and the increase of their sensibility is the immediate cause of the results.

The Biology of Colostrum.—J. Bauer has carried on a series of experiments as to the character of the albumen found in colostrum. The investigations were made according to the modern hemolytic methods of differentiating between albumens from different sources. He compared the biological reactions of cow's milk, cow's colostrum, and cow's blood serum, and also of human milk, colostrum, and serum. From his experiments he found that whereas the proteins of milk reacted differently from those of either of the other two, those of colostrum and blood serum were indistinguishable from each other. From this the author concludes that while the proteins of milk are formed in the breasts, those of colostrum are direct transudates from the blood serum of the mother.

A Clinical Form of Inertia After Delivery.—Voron and Gonnet give examples of a form of inertia uteri that is serious in its effect on the medical practitioner, but less so for the patient. After having ascertained that uterine contraction is perfect he suddenly finds that the patient is flowing slowly but steadily, and the uterus entirely relaxed, while the patient is in collapse. This condition lasts from one to three hours, and ends in perfect contraction, and the following day the patient is in good condition. Ergot has no effect on the uterine muscle, and hot douches are as useless. The only thing that gradually induces contraction is bimanual massage, with one hand inside the uterus and the other on the abdomen grasping the fundus.—*Réunion Obstetricale de Lyon.*

The Principal Methods of Tuberculization of Young Infants.—E. Terrien discards the theories of hereditary transmission of tuberculosis, or of its predisposition, and considers the sources of its transmission invariably contagious. Remove the healthy child from contact with his tuberculous parents and you can raise him as healthy as other children. Even latent tuberculosis is affected favorably or cured by removal to the country and good hygiene. The entrance of the disease by way of the intestine is much less frequent than has been believed, especially since milk has been so universally sterilized. The common ways of entrance are the pulmonary and the nasopharyngeal. We should bend our energies to the lessening of direct contagion and the control of the tuberculous subject himself.—*Annales de Médecine et de Chirurgie Infantiles.*

Book Reviews.

A System of Medicine by Many Writers. Edited by Sir Clifford Allbutt, K.C.B., M.A., M.D., LL.D., D.Sc., F.R.C.P., F.R.S., F.L.S., F.S.A.; Regius Professor of Physic in the University of Cambridge; Fellow of Gonville and Caius College; and Humphry Davy Rolleston, M.A., M.D., F.R.C.P.; Senior Physician, St. George's Hospital; Physician to the Victoria Hospital for Children; some time Fellow of St. John's College, Cambridge. Vol. V. Diseases of the Respiratory System. Disorders of the Blood. London: Macmillan & Co., 1909.

This, the fifth volume of the series—really the seventh, two of the preceding volumes consisting each of two parts—deals with diseases of the lungs, pleura, mediastinum, thymus, and blood. It contains nearly a thousand pages, none too many, considering the importance of the subjects treated of, but owing to the thinness of the paper the book is not bulky and not so heavy as many smaller volumes. Some changes and transpositions in the order of articles have been made in this edition, the article on Physical Signs of the Lungs and Heart being brought here from the fourth volume, that on Aerotherapeutics from the first, and the one on Intrathoracic New Growths from the sixth volume. It would have been more in line with the modern conception of the disease had the article on Pneumonia been transferred from this volume to its proper place among the infectious diseases along with typhoid fever, diphtheria, and other general infections with local lesions. The article on Lobar Pneumonia, however, even if out of place in this volume, is an exceptionally good one, if such a distinction can be made in a treatise in which the general average of all the contributions is so high. The original article, written by Dr. Pye-Smith, has been revised for this edition by Drs. Beddard and Eyre. The section on treatment is conservative, though on the whole hopeful. The authors are a little fearful of the open-air treatment, "excepting in the case of very vigorous patients," seemingly not appreciating the fact that "very vigorous patients" are less in need of invigorating treatment than are the asthenic. The quasi-specific creosote treatment is not mentioned, but opsonic therapy is favored.

Another excellent article is that on Pulmonary Tuberculosis, by Dr. Percy Kidd, Dr. William Bullock, and Dr. Noel Bardswell, the latter treating especially of the advantages of sanatoria. This article also is out of place in a volume of diseases of the lungs, for surely tuberculosis is a general disease with local manifestation. As well might leprosy be treated of disconnectedly among the diseases of the skin and those of the nerves.

In the brief article on Polycythemia, by F. Parkes Weber, no distinction is made between the so-called Vaquez's disease, or polycythemia myelopathica, and Osler's disease, or polycythemia megalosplenica—a distinction which possibly does not exist, yet one which is usually recognized by writers on this disease or symptom-complex.

The few defects in this volume, chiefly of classification, are of slight moment, and are not of sufficient importance to affect the value of the work as a whole. The matter is all here and excellently treated, and if it is out of place sometimes the reader will be able to find it by means of the general index when the work is completed. And here, if we may anticipate, it may be hoped that the general index will be more inclusive than that in the first edition, which was too brief and not as helpful to the reader as a general index should be.

Sprains and Allied Injuries of Joints. By R. H. Anglin Whitelocke, M.D., M.C. (Edin.), F.R.C.S. (Eng.); Honorary Surgeon to the Radcliffe Infirmary and County Hospital at Oxford; Lichfield Lecturer in Surgery in the University. London: Henry Frowde, Oxford University Press; Hodder & Stoughton, 1909.

Judging from appearance, this book is written by a man with a large clinical experience and with good powers of observation, but without an extensive knowledge of the work of others along the same line. It contains many good, practical points, but is marred by *post hoc* arguments, by some errors, by complex classifications, and by numerous rules deduced from the author's own experience, but not founded on sufficient facts. When the author says, "It cannot be denied," one is tempted to ask, "Why not?" He has seen three cases of fracture of the carpal bones; therefore he pronounces the fracture rare, and says that it cannot be diagnosed without *x*-rays; whereas other writers maintain that it is quite frequent, and can be diagnosed with as much certainty as many other fractures. He appears to know little of Duplay's bursitis. He condemns immobilization in sprains, on account of subsequent crippling, and yet gets good results from this treatment when the sprain is accompanied by a fracture. His readers can hardly share his terror of wasting of muscles. The best chapter in the book is that on internal derangement of the knee joint, which comprises about one-fifth of the whole. It is well and clearly written and free from the vagueness which usually surrounds this subject.

Practical Gynecology. A Manual for Nurses and Students. By Netta Stewart, Sister in the Gynecological Wards of the Royal Infirmary, Edinburgh, and James Young, M.B., F.R.C.S.E.; Clinical Tutor in Surgery and late Resident Gynecologist, Royal Infirmary; Physician to Lauriston Pre-Maternity Home, Edinburgh. Numerous Illustrations and Plates. New York: William Wood & Co., 1909.

The present work is a second and enlarged edition of "Gynecological Nursing," by Netta Stewart. It will be observed that its scope is enlarged to make it suitable for medical students. Nonoperative methods, such as douches, the vaginal tampon, etc., have been described in some detail. The book is well arranged and clearly written, and should prove serviceable to nurses; for medical students it may serve as an introduction to some larger text-book on gynecology.

The Influence of Heredity on Disease. With Special Reference to Tuberculosis, Cancer, and Diseases of the Nervous System. A Discussion Opened by Sir William S. Church, Bt., K.C.B., M.D.; President of the Royal Society of Medicine; Sir William R. Gowers, M.D., F.R.S.; Arthur Latham, M.D., and E. F. Bashford, M.D. (From the Proceedings of the Royal Society of Medicine, 1909, Vol. II.) London, New York, Bombay, and Calcutta: Longmans, Green & Co., 1909.

The discussion contained in this volume was the first held by the Royal Society of Medicine in a meeting of the society as a whole to consider questions of general medical interest. That the subject treated here is of general interest will readily be allowed, and that the discussion thereon is worthy of the subject and also of the distinguished contributors whose names are prefixed to the contents of the volume will be just as readily acknowledged by all who read this volume. Among the list of contributors to this discussion will be found the names of physicians and surgeons, pathologists and bacteriologists, biologists and pure scientists. The subject seems to have been viewed from every side, and the discussion, while dignified, was never dry and at times was both exciting and entertaining. We have read the volume with considerable interest and profit, and trust that it is but the first of a series.

Vorlesungen über Diätbehandlung innerer Krankheiten vor reiferen Studierenden und Aerzten. Von Prof. D. H. Strauss, Berlin. Mit einem Anhang "Winke für die Diätetische Küche" von Elise Hannemann, Vorsteherin des Haushaltungs-Lehrerinnen-Seminars und der Kochschule des Lette-Vereins in Berlin. Zweite, vermehrte und verbesserte Auflage. Berlin: Verlag von S. Karger, 1909.

The appearance of a second edition of Strauss's book on dietetics in internal diseases within one year after the first edition speaks by itself for the success of the book. Indeed, the lectures of the well-known internist seemed to have met a real want in this line of medical literature, for few other treatises of similar character have gained popularity so quickly. This edition consists of fifteen chapters, giving appropriate diets for gastritis of various origins, disorders of the chemical secretions of the stomach, peptic ulcer, neuroses of the stomach, mechanical, infectious, and reflex disorders of the intestinal tract, fevers, diseases of the genitourinary apparatus, and finally diseases of metabolism, such as gout, diabetes, etc. One chapter is devoted to obesity cures and another to the diet usually combined with so-called "rest treatment." We note that Strauss is inclined to favor Leube's milk diet in gastric ulcer in preference to the high protein diet of Lenhartz; in typhoid fever, too, he sides more with physicians who continue a strict fluid or semifluid diet well into the convalescent period rather than with those who give solids during the fever or as soon as the temperature has come down to normal.

A very practical appendix containing numerous "recipes" for dietetic dishes has been prepared by a principal of a cooking school in Berlin, and it forms a bulky addition to the lectures proper. Tables giving the caloric values and the composition of various standard articles of food are included. These features make the book acceptable not only to physicians, but also to nurses, dieticians, and intelligent lay people who may have patients under their care.

Society Reports.

MISSISSIPPI VALLEY MEDICAL ASSOCIATION.

Thirty-fifth Annual Meeting, Held at St. Louis, October 12, 13, and 14, 1909.

THE PRESIDENT, DR. JOHN A. WITHERSPOON OF NASHVILLE, TENNESSEE, IN THE CHAIR.

ADDRESSES of welcome were delivered by Dr. Tinsley Brown, president of the Missouri State Medical Society, and by Dr. Clarence M. Nicholson, president of the St. Louis Medical Society. The response on behalf of the association to these addresses was made by Dr. T. Hunt Stucky of Louisville, Kentucky.

The Treatment of Peritoneal Infections in the Light of the Protective Nature of Peritonitis.—Dr. CHANNING W. BARRETT of Chicago pointed out that the spreading and absorption of infection was a process dangerous to life, and that inflammation was a reaction beneficial to the patient in the presence of infection. He drew the following conclusions with reference to the treatment of peritoneal infections: (1) peritoneal infection could be prevented by the greatest care in operative work and by the approved use of such means as were best calculated to prevent peritoneal infection from other sources. An infected appendix was one which by reason of kinking, the presence of a foreign body, etc., was likely to become infected, and should be removed. Pathological conditions of the intestines, gall-bladder, uterus, tubes, and ovaries should receive attention. (2) In the presence of existing peritoneal infection an effort should be made to discover its origin and further infection prevented, if possible. (3) Easily and safely removable sources of infection, such as a badly infected appendix or in some instances an infected kidney, ovary, or uterus, should be removed But when this was done during the acute process it should be done, not because the structure was inflamed, but because the sources of infection were being thereby entirely or largely removed. (4) All physical activity of the patient, massage, peristalsis, etc., which would tend to distribute the infection should be avoided. (5) The development of bacteria in, and the distribution of the same through, the intestinal tract should be lessened by the removal of gaseous fluid contents of stomach by lavage, rectal flushings, and, if necessary, by enterostomy during the operation. (6) Whenever and wherever the area of infection could be reached, or whenever the infectious material existed in the general peritoneal cavity that could be drained, drainage should be established. The tendency of infection was to break down its limiting wall and to increase its area, and the damage done not only depended upon the virulence of the infection, but upon the area involved. The application of these principles to the treatment of appendical infection were (1) the removal of troublesome appendices before the acute onset of infection. (2) The removal of the infected appendix before any considerable peritoneal infection took place. (3) Drainage of localized appendical abscess, with the removal of the appendix, if it was easily found. (4) Drainage of the peritoneal infection with the removal of the diseased appendix, if easily found, if a localized wall had not formed, the absence of wall or weakness of wall making drainage very urgent. (5) Treatment of inflammatory wall as a benign and protective process in conditions interfering with the bowels in a mechanical way when it might have to be disturbed by the existence of the distributing infection. (6) Rest, general and local, emptying the intestinal tract, dilution of the toxins, and supportive treatment with salt solution should be made use of as in keeping with or without operative treatment.

Treatment of Tuberculous Peritonitis.—Dr. W. A. BRYAN of Nashville called attention to the time prior to the development of peritonitis, and to that subsequent to operation. In obscure conditions of the pelvis and right iliac fossa of mild grade, sufficient, however, to annoy the patient and to bring him to consultation, and where no physical signs or symptoms were present sufficiently to clear up the etiology, a diagnosis should not be ventured, and the treatment not begun until tuberculin was used to eliminate the possibility of tuberculosis. If it proved positive, even then it did not mean that the tuberculous process was acting at one of the two sites named, although a physical examination would enable one to determine with satisfaction on this point by the exclusion of others. By this means the process might be dealt with much earlier on the average and the results be much more satisfactory. His results had been most gratifying in the accidentally discovered cases and in those where an early operation was done on suspicion of tuberculosis. Surgery was usually accepted by the laity and too often by physicians as an ultimate resort, which, if it did not terminate in death by operation, would surely give complete relief. This was largely true in general work. But not so in tuberculous peritonitis. We might excise the primary focus, but we dared not attempt eradication of the infection from the whole cavity. When this primary focus was withdrawn the individual was not cured, but only placed where a cure might occur. All cases operated on for tuberculosis should be treated subsequently by physicians.

Dr. A. J. OCHSNER of Chicago said that after observing thirty-two cases of tuberculosis for a considerable time in order to ascertain the ultimate results, his conclusions were that taking every case of tuberculous peritonitis and treating it as we treated tuberculosis generally after surgical operation for the removal of the primary focus, about 50 per cent. or more would get well and remain well.

Dr. J. HENRY CARSTENS of Detroit said it was not the tuberculosis itself that killed the patient, whether it was tuberculosis of the lungs or any other part of the body, but it was a mixed infection and whenever we had a tuberculous condition in the abdomen, involving the tube or appendix, the patient was in danger of having added to that some other infection. If the appendix was the cause of the trouble it should be removed. If the trouble was in the tubes and there was mixed infection, they ought to be removed. Patients who were operated on for tuberculosis should be treated after operation, like all other tuberculous patients.

Dr. H. TUHOLSKE of St. Louis stated that in addition to any surgical work it might be necessary to do in these cases of tuberculous peritonitis, general and supportive treatment should not be neglected.

Dr. A. H. CORDIER of Kansas City, Mo., said there must be something connected with surgery itself that had a marked curative effect in these cases of tuberculous peritonitis.

Dr. RICHARD A. BARR of Nashville said the primary tuberculous focus should be within the abdomen and removed surgically if we would expect to get satisfactory results.

Tuberculous Toxemia in Surgery.—Dr. ALEXANDER C. WIENER of Chicago presented the following therapeutic conclusions: (1) Obstruction of the respiratory organs which curtailed the intake of air were to be removed by the nose and throat surgeon. Too much stress could not be laid on the removal of enlarged tonsils and adenoids by the skilled operator. Other anomalies, such as phimosis, should be remedied. (2) Mechanical treatment should be undertaken to correct all deformities of the skeleton, particularly the spine and chest. Children and adults who began to develop round shoulders with the subsequent hollows below and above the cavicles, needed urgent treatment. It was harmful to advise the wearing of apparatus

for support during the growing period. Braces should be discarded as therapeutic agents in the treatment of deformities of the spine due to rickets. Instead treatment should consist of (*a*) complete mobilization of all the intervertebral and vertebrocostal joints. (*b*) Correction of deformities of the vertebræ and ribs. (*c*) Active and passive exercise of the respiratory muscles, including the diaphragm.

Dr. F. M. Pottenger of Monrovia, Cal., said the more we studied the infection in tuberculosis the more we came to the conclusion that infection took place in a great number of people early in life and that most of us went through life with at least quiescent foci of tuberculosis within our bodies. These quiescent foci were not always negative and they did produce symptoms which had not been generally recognized. Toxemia in young neurasthenic school girls was undoubtedly due to latent foci of tuberculosis and he had seen a number of such cases get well after treatment for tuberculosis.

Elements of Success in Surgical Work.—Dr. A. H. Cordier of Kansas City, Mo., in a paper on this subject drew the following deductions: (1) The field of surgery was a vast one and was best covered by the specialist in some of its departments, the eye and the ear especially. (2) Surgery and medicine should go hand in hand in the treatment of borderline cases, but should be divorced in the strictly surgical or medical cases. (3) The selection of a surgeon for a given case should be from no other standpoint than that of his recognized ability. (4) A surgical operation should be performed as quickly as possible, consistent with good and completed technique. (5) All unnecessary and rough handling of important tissues and organs should be avoided. (6) Careful short anesthesias would help to keep the death rate low. (7) Careful hemostasis with proper ligature material was an important element in successful surgery. (8) Thorough aseptic tecnique should be carried out and might be obtained either with or without rubber gloves and mask. (9) Lawn tennis suits and gloves were only too often the avenues leading to wound infection. (10) Short postgraduate courses instilled false surgical confidence and led to many surgical disasters. (11) Honesty and sincerity should ever be the keynote in deciding as to the advisability of performing any surgical operation. (12) Mental tranquillity of the patient was of much importance preceding the performance of some surgical operations.

Dr. J. Henry Carstens of Detroit said no one had a right to practise surgery, and especially abdominal surgery, unless he had been an assistant for at least one year with some first-class surgeon in a hospital where he had seen hundreds and hundreds of operations and had witnessed the troubles, trials, and complications that were met with. Educated people knew and found out who were the good surgeons. The general practitioner ought to know who was a good surgeon and ought not to trust everybody to perform operations which were attended with great danger to life.

Dr. M. C. McGannon of Nashville stated he was not willing to admit that the surgical work of the pioneer was as good as that which was being done to-day. The enthusiasm of youth led many a recent graduate to rush into the field of large surgery where he had better keep out until better trained. But how were we to stop that? It was the duty of this and other societies to adopt such measures as would prevent enthusiastic young men from rushing into a field of work that they could not fill. Many of us had had an opportunity of seeing disasters following the surgical work of inexperienced men.

Dr. Channing W. Barrett of Chicago said surgery had come to occupy a large place in the world and it was our business, as members of the medical profession, to see that our surgical work was made just as successful as possible. The time had gone by when a man could plunge into surgical work and kill patients in order to learn how to do surgery. The opportunities for learning surgery now were too great and too cheap to permit of inexperienced men operating, and surgeons were only too willing to train those who wished to become surgeons.

Conditions Simulating Surgical Diseases.—Dr. M. C. McGannon of Nashville related some recent experiences and said that it was not often that a surgeon was called upon to reverse a diagnosis of chronic peritonitis in favor of spinal neurosis of traumatic origin and yet such was his experience with a case brought to his attention a few months ago. He cited cases of appendicitis that had been on many occasions confounded with pleurisy and pneumonia. Many authors had called attention to the fact that pain associated with pneumonia and pleurisy, especially in children might, if referred to the abdomen and, if right-sided, occasion a diagnosis of appendicitis. It had been his fortune to have had two such cases referred to him for operation, and in which appendicitis was so closely simulated as to deceive some good practitioners.

Dr. Edwin Walker of Evansville stated he was reminded of a case where a man had locomotor ataxia and the proposition was made to operate on him for gallstones. The patient afterwards fell into the hands of a surgeon who operated for gallstones, but no gallstones were found. This man subsequently died of acute pneumonia and from extension of the ataxia.

Dr. J. Henry Carstens of Detroit said that two years ago a woman was brought to him with large fibroid tumors. She had been vomiting for three weeks, off and on, and could not sleep. He ran his finger over the clavicles and over the tibiæ, found they were painful, gave her one-quarter of a grain of bichloride of mercury hypodermically every day, and in four or five days she was able to sleep well, the vomiting ceased, and the fibroids had nothing to do with those symptoms. He saw a man who was supposed to have had gallstones. He looked at his tongue, saw a blue line along the edge of it, and said to him, "You are a painter, are you not?" and he replied, "Yes, sir." He told him he was not suffering from gallstones, but from lead poisoning.

Dr. J. Rilus Eastman of Indianapolis said the general practitioner and internal medicine man ought to be educated along these lines. He went with two competent physicians in the summer in the country to examine a little girl whose case was diagnosed as appendicitis. A mass had been described as present in the right groin. The little girl was eleven years of age, and these physicians considered it a clear case of appendicitis. While he sat at the bedside she took her handkerchief, expectorated profusely, and it proved to be tuberculosis.

Dr. Richard A. Barr of Nashville was called to the country a year ago to operate for appendicitis, the operation having been delayed for a number of days. The patient had been sick for ten days. On examination, he decided that this patient did not have appendicitis, but typhoid fever, and was able to persuade the attending physician that he was correct, and no operation was done. He took some of the patient's blood with him, had it examined, had a Widal reaction made, which proved to be negative.

Dr. William B. Burns of Memphis stated he had seen two or three cases presenting symptoms of appendicitis which were as positive as we usually see them, but examination of the blood showed the presence of malarial parasites, and hypodermic injections of quinine in four hours removed all the symptoms.

Surgery of the Gall-Bladder.—Dr. W. D. Haines of Cincinnati, after including a comprehensive survey of the anatomy and pathology of the stomach, duodenum, and pancreas in connection with surgery of the gall-bladder, said, in reference to cholecystectomy: The first essential

was to secure the cystic duct and artery in the grasp of a long hemostat placed near the junction of the cystic with the hepatic duct. Another hemostat was placed a short distance before the first, and the cystic duct and vessel were divided. The first hemostat would control hemorrhage, and the second would serve as a retractor in the succeeding steps of the operation. Incision of the peritoneum for stripping up the gall-bladder should be made in the fold where the peritoneum was reflected from the gall-bladder to the liver, in order to preserve sufficient tissue to cover the raw surface of the liver. If unusual difficulties presented themselves in ligating the cystic artery, the hemostat might be left in place for forty-eight hours. The denuded surface of the liver was now covered by sutures of divided peritoneum, and a rubber tissue covered drain placed in the bottom of the wound. A large vein, sometimes mistaken for the portal, was occasionally found crossing the ducts, which, if present, was almost invariably injured in the course of the removal of the gall-bladder. It should be clamped, doubly ligated, cut, and the end retracted, as hemorrhage in the bottom of the wound was difficult to control, caused delay, and added to the shock of the operation. In closing the abdomen the peritoneum and posterior sheath of the rectus were included in the first tier by a buttonhole or interrupted suture. Two or three figures of eight silkworm gut sutures should be placed so as to include the muscle, the fascia, and skin, but were not tied until the anterior fascia was closed by continuous catgut.

The Latent Gallstone.—Dr. Chas. N. Smith of Toledo said that, in the light of our present knowledge of the initial symptoms of gallstone disease and of the slight or characteristic symptoms of latent gallstones, we must believe that in every case they have produced, do now produce, and will continue to produce a certain train of symptoms so distinctive in their nature that a positive diagnosis depended only upon a correct interpretation of them. The three symptoms which were mentioned almost invariably when cholelithiasis was in consideration were colic, jaundice, and putty-colored stools. Every one of these symptoms was a late or terminal event, occurring after a more or less prolonged period of occupancy of the gall-bladder by the stone, during which period distinctive and diagnostic symptoms were present, and should be correctly interpreted. One of the most important advances in the surgical treatment of diseases in the upper abdomen accrued from the recognition of the fact that 80 per cent. of the cases of chronic pancreatitis were the result of gallstones and the sequentially occurring infections of the biliary tract. Medical and hydropathic treatment, both confessedly powerless in so far as absorption or removal of the concretion was concerned, aimed only at the control of the symptoms through abatement of the infection. Surgery, advancing on the limited possibilities of medicine, by one safe and eminently successful procedure removed simultaneously the causal gallstones and the resultant infection.

Latent Duodenal and Gastric Ulcer.—Dr. Willard J. Stone of Toledo said duodenal and gastric ulcers were more common than was supposed. Most of them were masked under the symptoms and diagnosis of functional hyperchlorhydria. The acute forms, with severe recurring hemorrhages, in certain cases demanded surgical interference, although such patients were in an extremely critical condition and the surgical risk extremely hazardous. Many recovered under medical care. Perforation demanded, first of all, early diagnosis. Fully 60 per cent. were wrongly diagnosed as appendicitis, ruptured gall-bladder, intestinal obstruction, or acute peritonitis, not stating the cause. The earlier the interference the better was the result. Goldstucker, who had recently reviewed 236 cases of perforation, found that of those operated upon within the first twelve hours the mortality was 29 per cent.; after twelve hours the mortality was 54 per cent. Robson found among 155 cases of perforating ulcer in the literature to 1907 that the mortality among those operated upon during the first twenty-four hours was 37.7 per cent.; after twenty-four hours the mortality was 85.5 per cent. In about one-fourth of the cases in the literature of perforating duodenal ulcer no previous dyspeptic symptom suggestive of the condition had existed. Fully 75 per cent. of uncomplicated ulcer of duodenum or stomach were cured by medical means, the remaining 25 per cent. became chronic, and might be classified under (1) chronic ulcer with active symptoms, such as pyloric spasm, scar contraction, perigastric adhesions, or malignant transformation; (2) chronic ulcer with latent symptoms, which might be defined as that type which gave rise to periodic attacks of distress at the height or end of gastric digestion and simulated in a large percentage of cases neurotic or functional hyperchlorhydria. Hemorrhage or vomiting was not necessarily a symptom of chronic ulcer. The attacks were periodic, lasting a month or two, with recurrence after two or three months. The distress was relieved by taking food, milk, or alkali. Supersecretion, which was a far more important diagnostic sign than hyperchlorhydria (which existed in about one-half the cases), was practically always present. The finding of 50 to 100 c.c. hyperacid secretion in the fasting stomach was extremely suggestive of ulcer. Patients often complained of raising a mouthful of acid secretion from the stomach when the organ was supposedly empty. Elaborate laboratory investigations were not necessary. The longer the pain was relieved by food, the more probable was the lesion duodenal rather than gastric. The typical pain of chronic duodenal ulcer occurred from 3 to 5 hours after a meal. Pyloric stenosis in infants, when due to pyloric spasms from hyperacid contents (not the true congenital stenosis due to hyperplasia) might be the result of reflex irritation from a pyloric or duodenal ulcer. In an infant of six weeks dying in thirty-six hours with symptoms of laryngismus stridulus and pyloric obstruction, an ulcer one centimeter in diameter was found in the duodenum just below the pyloric ring. The differential diagnosis in general excluded cholelithiasis, and, in particular, functional nonorganic hyperchlorhydria. Chronic ulcer of duodenum and stomach was not, as a rule, cured by medical means. Such patients might, however, barring the contingency of severe hemorrhages or perforation, be fairly comfortable with a carefully regulated diet and appropriate medical treatment. If these measures failed after a reasonable time, surgical aid offered the best hope for cure when performed by those experienced in the surgery of the upper abdomen.

Dr. A. J. Ochsner of Chicago said our attention had been directed constantly to the fact that we must look for gallstones, without complications, without the impaction of the stones in the ducts, whenever a patient complained of gastric symptoms, and that we could count on an early diagnosis in the majority of cases from now on. The mortality which followed operations for the removal of gallstones was small now as compared with what it was six or eight years ago. At that time patients were operated on who were suffering from cholangitis. Another reason why the mortality was small now was that fewer harmful things were done during the operation. The gallstones were simply removed and drainage established.

Dr. R. A. Bate of Louisville said if we went back to the origin of gallstones, there was absolutely no reason why medicine should not remove every gallstone which was composed of 90 per cent. cholesterin. If the gallstones were differentiated, those that contained bilirubin calcium in greater proportion than 10 per cent. might re-

quire surgical interference. Gallstones were formed in the gall-bladder and in the ducts in very much the same way as mucin, and when stagnation of bile occurred the mucin caused putrefaction of the bile, and this, in turn, permitted the microorganisms, which were not very hard to overcome, to pass up, and wherever cholesterin was deposited by the lecithin being broken up, the lecithin held the cholesterin in solution. There were three factors to consider in connection with gallstones: Microbes of various kinds, alkalies, and the acids.

Dr. H. Tuholske of St. Louis said that a fairly large personal experience had taught him the important lesson that a gall-bladder with stones in it could be relieved when the stones were mechanically taken out. He had spent considerable time at the great Mecca of the gallstone sufferers, Carlsbad. He had heard people say that there were enough gallstones passed in Carlsbad to pave the streets with them. He came in contact with the best men of the profession there, had talked with them about gallstone cases, and he was sorry for any man or woman who had a gallstone that went traveling and left its comfortable little bed in the gall-bladder, for then trouble was likely to begin. There was danger of lodgment in the narrow duct. There was danger of ulceration and perforation. Then came all the obstructive symptoms, the adhesions which muddled the picture and produced a serious condition. Where the gall-bladder was in a fair condition the dangers incident to the removal of the stone or stones was not great. The presence of gallstones not infrequently caused a change in the epithelium of the gall-bladder, and we might find the typhoid bacillus as a nucleus in the gall-bladder. All things considered, when a diagnosis of gallstones was made, it was better for the individual to have the stones taken out.

Dr. Daniel N. Eisendrath of Chicago said that while olive oil had its function, there were cases where, either through some condition of the patient or complication, or some voluntary objection to the operation, the patient would not consent to operation. Such patients were benefited temporarily by olive oil and the Carlsbad waters; but let there be obstruction produced by the gallstones, or let there be retention of secretion, one found a hyperemia and all the pathological processes incident to obstruction. What happened? There were cases of gallstones in which the common duct stone became impacted, stayed so for a few days or a few weeks, and went back again. Fenger called attention to this under the head of intermittent jaundice in connection with common duct stones. Carcinoma not infrequently developed from the constant mechanical irritation of a gallstone or gallstones. The only reliable and satisfactory treatment for gallstones was to remove them.

Dr. J. Henry Carstens of Detroit said it was an outrage for a general practitioner, or for a specialist in gastrointestinal diseases, to treat patients month after month and year after year in different ways, without making a correct diagnosis. It would redound to the credit of such men to say, when they were in doubt, "I do not know whether you have duodenal ulcer or ulcer of the stomach, and I think you ought to go to an abdominal surgeon, who can make a small opening and find out whether you have gallstones or not. If you have, they can be taken out. On the other hand, if it is an ulcer, it can be excised, the opening closed, and a cure effected."

Dr. Thomas B. Noble of Indianapolis said several years ago he had the privilege of doing a pelvic operation which necessitated a suprapubic incision. During this operation he discovered two stones the size of marbles in the free gall-bladder. Directly thereafter that woman was given phosphate of sodium for one year. For another year she took olive oil three times a day, after which she was seized with intense pain, due to a stone blocking the cystic duct, and an infected gall-bladder. He had to do an emergency operation, and he found these stones of the same size and the same character that they were two years previously. Previous to that time he was not very much in favor of medical treatment in cases of preformed stones, and he was less so now.

Dr. Richard A. Barr of Nashville said olive oil must be brought in contact with the gallstones to do any good, and one might as well rub olive oil on the outside of the abdomen as to give it internally, so far as any effect it would have on preformed gallstones was concerned.

Dr. M. C. McGannon of Nashville said a member of the medical profession came under his observation two years ago as a patient who had had persistent jaundice for three months. It was not accompanied by pain. He was quite yellow at the time he came under observation. He had lost flesh, and it was thought that he might be suffering from cancer. A diagnosis of cancer had been made by a very good internal practitioner. When the man came under observation Dr. McGannon was quite willing to agree with the internist in the supposition that it was a case of cancer, but the patient, being a doctor, he put this argument before him: "If this is a cancer, you will certainly die from its effects. If it is not cancer, and you submit to an operation, we may be able to give you relief If we do not give you relief, we at least will do you no harm. We will not shorten your life with an exploratory incision to determine the character of the trouble." The operation was consented to and performed. The gall-bladder was found to be completely shrunken, the duodenum involved in a mass of adhesions bound down into a knuckle formation about the gall-bladder and liver. The breaking up of the adhesions was effected with a great deal of difficulty. The stomach was opened in the dissection, but closed at the time. The breaking up of the adhesions relieved the condition. The gall-bladder was removed, and to-day that gentleman, after four years, is able to ride horseback, and is practising medicine in the State of Tennessee.

(*To be continued.*)

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, Held October 7, 1909.

The President, Dr. John A. Wyeth, in the Chair.

The Etiology and Symptomatology of Peptic Ulcer.—Dr. Charles G. Stockton of Buffalo read this paper. He said that the most important recent contribution was that of Weinland, who maintained that there was formed in the gastric mucosa an antibody, an antipepsin, which opposed the digestive action of the gastric juice: he held that, for some unknown reasons, there occurred in certain areas of the mucosa a deficiency of these antibodies and that the stomach, thus unprotected, was readily injured by the corroding effects of the gastric secretion. Gastric ulcer occurred in women somewhat more frequently than in men, and was seen more often in women between the fifteenth and thirty-fifth year, in men between the twenty-fifth and fiftieth year, but it might occur at any age. Occupation seemed to have but little bearing on the matter. Anemia favored the appearance of peptic ulcer. Hyperhydrochlorhydria was present in the majority of these patients. Local injury of the stomach had been held as an important etiological factor, but the claims seemed to have but little basis for foundation. Superficial burns undoubtedly excited duodenal ulcer, and the reason was unknown. There was something peculiar to the stomach by means of which it was protected from the gastric juice. There was some factor, too, that destroyed the inherent protective influence in the area of ulcer, and to explain this he turned to the doctrine of Weinland, that there was a protecting antibody developed in the stomach for the preservation of the

lining. But after accepting this there remained the need of an explanation for the focal disappearance of the antibodies in isolated regions wherein round ulcers developed. This was the unknown element in the etiology of gastric ulcer. It seemed to him that the best explanation for this local disappearance of resistance in the stomach might be found by including in the group of factors of the pathogenesis the element of trophic neurosis. Through the influence of the nervous system the circulation might be temporarily or continuously disturbed, thus leaving the part vulnerable to the action of the gastric juice; or including Weinland's theory, through the nervous system the development of antibodies in a certain region might be inhibited as the result of which the tissues would be attacked and round ulcer would follow. Dr. Stockton said that he was aware that this suggestion had met with opposition in certain directions, but it had never been satisfactorily excluded from the possibilities and, in his judgment, of the probabilities of the case. He believed that the essential factors in the cause of gastric ulcer included certain systemic predisposing conditions, among which were chlorosis and hyperchlorhydria. He also believed that resistance as to digestion was lost in certain small areas through the intervention of a trophic neurosis interfering with the circulation or the normal nutrition of the part. Peptic ulcer was at times surprisingly devoid of symptoms. As a rule there was pain, often paroxysmal and intense. This pain was made worse by eating. In duodenal ulcer severe pain was apt to occur two or three hours after taking food. The location of the pain in gastric ulcer varied with the position of the stomach. It was usually found below the ensiform and rather to the left of the median line. Vomiting was usually acid in character, followed the taking of food, and generally relieved the pain. The appetite might be good. There was constipation. In the stools blood might be found. Hemetesis was not a proof of ulcer, even when abundant. The stomach contents usually showed a very high secretion of hydrochloric acid. The high acidity was very often a result of over retention of gastric contents and not necessarily from excessive secretion of hydrochloric acid. The delay in the onward passage of the acid chyme depended upon pyloric spasm. One might differentiate between ulcer and gastric crisis in that the latter appeared suddenly with great intensity and with intervals of perfect health. The pain of cholecystitis might be excluded by its location, its radiation, the difference in point of tenderness, the accompanying hepatic disturbances, and often the presence of urobilin. Gastralgia or hysterical pains were generally relieved by pressure. The pain of hyperchlorhydria occurred toward the end of gastric digestion, or when the stomach was empty; it was relieved by taking food, was accompanied by only moderate tenderness and was diffused in location. Pyloric ulcer, often chronic, was as much duodenal as gastric. It was often impractical to differentiate between pyloric and duodenal ulcer, but sometimes this might be done through finding blood in the feces while none appeared in the stomach contents.

Surgery of the Gastric, Gastroduodenal, and Duodenal Ulcers.—Dr. JOHN B. MURPHY of Chicago said that from a surgical standpoint he deemed it advisable to include under the same heading all of the pathological conditions above mentioned, because the pathology of the one often overlapped or merged into the pathology of the other, and frequently both gastric and duodenal ulcers were present; because the symptomatology of the one so closely resembled that of the others that it was often impossible to make a differential diagnosis; because all required surgical procedures for their cure, in about equal frequency; because the initial operative incision should be made in the same direction and position, and because the immediate and final clinical results, under given conditions, were equally favorable and dangerous. The relative frequency of each was variously estimated by individual surgeons depending upon their experience. It doubtless would not be long until the number of duodenal ulcers observed surgically would exceed the gastric ulcers. The relation of sex in gastric ulcer was: Males, 40 to 45 per cent.; females, 60 to 65 per cent. In duodenal ulcer: Males, 60 to 70 per cent.; females, 40 to 30 per cent. Gastric and duodenal ulcers were most frequent between the ages of thirteen and forty-three. The indications for surgical intervention were best divided to fit three classes of operations, emergency, elective relief and curative, and prophylactic operations. The general indications for operations were (1) acute, recurrent, and chronic hemorrhages; (2) continued and frequent emesis; (3) perforations; (4) continued symptoms or frequent recurrences of them, indicating open gastric or duodenal ulcer that did not respond to well directed medical treatment. This did not apply to the ulcers occurring in girls between the ages of twelve and twenty years; (5) pyloric stenosis, due to cicatricial contraction, perigastric adhesions, or pyloric or duodenal flexures; (6) pyloric retention, due to (*a*) reflex spasm and (*b*) pyloric suspension by short pylorohepatic ligament; (7) gastrectasis. Cases of gastric neuroses without physical, chemical, or bacterial evidences of disease should never be operated upon. He was of the belief that acute hemorrhage was much more frequently a cause of death than was generally accepted. Excision of the ulcer usually gave the best results. When this was not practical or possible, ligations of the trunk vessels should be made in the neighborhood of the ulcer. If this did not appear satisfactory gastrotomy and suture of the surface with inabsorbable material should be resorted to. In chronic recurrent hemorrhages the ulcers were usually free from adhesions and were favorable for excision; the operation of election. In the operation for continued emesis an enteroenterostomy should be performed at the same time as the gastroenterostomy. Perforations of the stomach occurred most frequently on its anterior wall and in the pyloric zone. The duodenal perforations were practically all on the anterior wall of the first portion. In cases of perforative gastric and duodenal ulcer operation should be done within a few hours after the perforation had taken place. The severe pain, the reflex nausea and vomiting, the fixation of the abdominal muscles, the restrained diaphragmatic action, the flat piano percussion note, the absence of peristaltic sounds in the infected region, the frequent absence of or diminished hepatic dullness, the great sensitiveness to perpendicular percussion impact, the anxious expression, the slight elevation of temperature, the leucocytosis, etc., positively indicated a surgical lesion in the upper abdomen demanding prompt surgical interference. Operations performed thirty to forty hours after perforation had a mortality of upward of 90 per cent., while those performed within sixteen hours after perforation had a mortality well under 10 per cent. Summarized, the elements essential to success were early operation; closure of the perforation; rapid operation; avoidance of peritoneal handling, sponging, or irrigation; continuous drainage; Fowler position; immediate restoration of blood pressure by intravenous salines; retention of normal blood pressure; blood-washing and elimination through continued proctolysis. The operations for the relief or cure of continued ulcerations, pyloric stenosis, pyloric retention, gastrectasis, gastric fixation, etc., were all essentially operations of election. The symptoms of these diseases were sufficiently characteristic in a considerable proportion of the cases to justify a positive diagnosis. Granting that the cases were pronounced surgical, what operations should be performed for the immediate relief of, and for the prophylaxis against, secondary lesions and recurrences? These operations were

divided into (1) gastroduodenostomy, (*a*) Finney operation, (*b*) oblong button with anterior row of sutures for the relief of tension, and (*c*) Heinike-Mikulicz; (2) gastroieiunostomy, anterior and posterior. The mortality in experienced hands varied considerably, dependent somewhat on the technique more than on the conditions, and the judgment as to the degree and type of the operative procedure. The larger the ulcer and the closer its relation to the pylorus, and the more disturbed the physiological function of the pylorus the greater and more continuous was the relief. The small ulcers situated a distance from the pylorus, and a few of the larger ones, were not symptomatically materially changed by the operation. In the future the results would be vastly improved as the cases would be brought to the surgeon before the pathological changes had advanced beyond the likelihood or possibility of surgical repair.

Gastric Ulcer in the Young.—Dr. A. Jacobi said that the anatomy of gastric ulcer and the principles of its treatment were in the main essentially the same in all periods of life. Among the causes he considered prenatal disposition. Defects in the wall of the stomach were occasionally, though rarely, met with. Another cause was thrombosis of the umbilical vein and of its small ramifications, and local embolism in the wall of the stomach, some of which depended upon congenital diseases of the heart. Thrombosis and emboli were frequent causes of fatal melena. The worst cases of melena were those of sepsis. When melena did not directly destroy life Dr. Jacobi had seen it give rise to extensive erosions and ulcerations weeks after, with subsequent death. Kinnicutt had spoken of the causation of gastric and duodenal ulcer by burns and by septicemia, particularly when complicated with nephritis, the frequency of which was most commonly found at the two extremes of life, old age and after birth. It was very probable that such of the causes of stenosis of the pylorus in the newborn and very young dependent upon spasm caused by hyperacidity might give rise to ulceration. Local injuries caused ulcers, such as were produced by swallowing foreign bodies. Infectious fevers had been charged with causing gastric ulcers. Tuberculous ulcerations had been found near the pylorus, but Dr. Jacobi had not seen one in a child. Of the symptoms, pain was the most common, and was caused by oversecretion by undue peristalsis, or by pressure. Pressure on the full or empty stomach revealed it in the median line, or slightly to the left, below the ensiform process mostly. Eating caused it immediately; it continued during the meal and until the stomach got rid of its contents. Pain arising half an hour or an hour after a meal meant duodenal ulcer or peritonitic adhesions of the duodenum. Pain starting three or four hours after a meal should be referred to the colon. Pain while the stomach was empty, which was quieted by eating, meant a neurosis. Vomiting was not so frequent in the young as it was in the adult. It was mainly caused by hyperacidity. The suggestion that it was the ulcer which caused, and was not caused by, an excess of hydrochloric acid Dr. Jacobi did not believe to be correct. In a few cases there was no hyperacidity, but anacidity. Hemorrhages behaved as they did in adults, but they were rare. The nature of the disease being the same at all ages, the principles of treatment were the same. A diseased organ must not work; it must rest. An acute case required rest in bed; small doses of morphine should be given. Hemorrhages required starvation, ice on the stomach, a dose of morphine and adrenalin which, however, was useless when swallowed. In a few very bad hemorrhages, like those occurring in pulmonary cases, he had seen a favorable effect from ligating the venous circulation of the lower extremities. In chronic cases the cause should be looked after. No solid food should be given; in very bad cases milk only should be given. Fresh buttermilk was advisable. The meals should be many and not large. Medicines were required to keep the stomach alkaline. Magnesium oxide, with or without bismuth, was best adapted for neutralization. The proper preparation of bismuth was the subcarbonate. Excessive peristalsis and pain demanded the use of an opiate. Instrumental treatment he could not advise. Silver nitrate was a good remedy in protracted and relapsing cases. The after treatment might require iron.

The Diagnosis of Gastric Ulcer.—Dr. Max Einhorn demonstrated an apparatus for detecting gastric ulcers.

Dr. Joseph A. Blake believed that the chronic ulcers, that is, the so-called callous or indurated ulcers, belonged to the province of surgery rather than internal medicine. The reaction of repair to the intensely irritating gastric secretions was excessive, resulting in the formation of an extraordinary amount of connective tissue. The contraction of this tissue literally fed the walls of the stomach into the ulcer, where they were gradually destroyed. The puckering and contractions of the stomach observed in old cases of ulceration were evidence of this fact. The contraction of the scar tissue cut off the vascular supply in exactly the same way as happened in an indurated ulcer of the leg, consequently the ulcer perpetuated itself, and it was idle to suppose that treatment short of removing the indurated scar tissue would suffice. This excessive formation of scar tissue was familiar to all surgeons of experience in the surgery of gastric ulcer, and anyone who had observed the enormous amount of scar tissue formed in the neighborhood of a slowly penetrating ulcer would appreciate its importance in perpetuating tissue denutrition and consequent ulceration.

Dr. Wm. Van Valzah Hayes firmly believed that in the average case patients suffering from gastric or duodenal ulcers should be given the benefit of careful medical treatment if the disease had not been of too long duration. Failure to respond to such treatment after a reasonable length of time necessitated the opinion of a competent consulting surgeon. He regarded the diagnosis in atypical cases of gastric ulcer as somewhat difficult and at times wellnigh impossible. One physician, after studying for a time with Mr. Moynihan, made the statement that the diagnosis of duodenal ulcer seemed to him one of the easiest and that of gastric ulcer one of the most difficult to determine. Chronic appendicitis with pyloric spasm, painful digestion, and the various other symptoms due to marked acidity might closely simulate gastric ulcer. Pyloric spasm might be due to concretions within the appendix, or frequently to tuberculosis of the appendix.

THE NEW YORK PSYCHIATRICAL SOCIETY.

Regular Meeting, May 5, 1909.

The President, Dr. August Hoch, in the Chair.

Some Clinical Varieties of Periodic Drinking.—Dr. Pearce Bailey read this paper (see p. 724).

Dr. Meyer said this presentation of dipsomania was the fairest and sanest that existed to his knowledge. It was a very unfortunate thing that physicians were so prone to try for one explanation and to hit upon the explanation by the most unknown quantity that we might have, so far as the interpretation was concerned. Certainly this analysis should relieve us of the effort to explain everything by epilepsy *à la* Lombroso. The speaker could give some very interesting instances of the psychasthenic type of sprees, the feeling of inefficiency, of being at a disadvantage, fears, impulses, then drinking, then a spree, winding up in sexual debauch, etc., also seen in the manic-depressive and other types. The great difficulty was in the handling of the situation. This was a matter which Dr. Bailey had not brought into his paper, and which the speaker thought, therefore, he had better not bring up for discussion.

Dr. Hamilton said he had been much interested in Dr. Bailey's paper because his views were in accord with those of Kraepelin and the speaker in regard to the epileptic nature of this kind of episodic drinking, for there was certainly a similarity between certain forms of periodical drinking and masked or psychic epilepsy. In this connection, when looking over some of his cases, he had found something that impressed him as highly significant from a diagnostic point of view—a decided increase in the activity of the pupillary reflex, a tendency to dilatation; this he had seen in many epileptics, and he thought Reynolds and others regarded it as quite common. In three alcoholics whose debauches took the form of periodical seizures and were associated with much excitement, it amounted to a true hippus. One of these men would disappear for several days, and when found there was always retrograde amnesia. In regard to the sexual excesses and perversion referred to by Dr. Bailey, he was very familiar with these and with their medicolegal relations, and regretted that they were so often misunderstood. One case was here referred to last year by Dr. Hirsch, and seen by us both, as well as by others here present. It was that of a man who was a mild paranoiac, but when drunk he would undergo a sexual change. Upon one occasion he committed lust murder, cutting a hole in the abdomen of his victim through which he had connection. In other examples the action of alcohol was to exaggerate existing delusions. In a recent case seen by the speaker an individual who, though he entertained mild delusions against a former employer, based to some extent upon fact, and could ordinarily control himself, when excited by liquor shot the other without a word. Upon other occasions there had been hallucinosis, but many thought the crime was one that was due to ordinary drunkenness. This man was ultimately sent to an asylum, where he was now. In addition to the paranoid condition, there were pronounced physical signs of chronic alcoholism.

Dr. Dana said that he heartily agreed with all he had heard of Dr. Bailey's paper. He would think, from the sentiments expressed, that his paper would be of help in counteracting somewhat the formal cry which was always put forth about inebriety—that it was "a disease," as though it was something like rheumatism or a broken leg or something quite beyond the person's help. For, although inebriety might be called a disease, in a certain sense, it was often a condition in which the individual was somewhat at fault and had a certain responsibility. While he quite agreed with the statements that Mr. Bailey made about the psychogenic factors, he thought we must also remember that sometimes this psychogenic factor of the psychosis was the habitual use of alcohol; that is to say, it happened that young men gradually got into the habit of drinking excessively; it was first only a careless habit, but after a time it became a distinct case of inebriety in which there came upon them distressing compulsions and impulsions. He recollected a case in which a young man had indulged in alcohol for some time; he finally stopped, for he was a very intelligent man, a lawyer, as he saw the injury he was doing himself. After that he used to have come upon him periodically in certain environments, *e. g.* when he went into the subway, states of the most horrible depression which would last for one or two hours; these depressions were promptly relieved by drink, and it was with great difficulty that he refrained from going into excesses as the result of these craving depressions. If he had not fought his inclinations, he would have become a periodical drinker; but by the exertion of his will he managed to save himself. In that case the psychogenetic factor of the psychosis was really the alcohol that he used first simply as a social habit.

Dr. Kirby said that in hospital practice an important group of cases showed the relation of some forms of periodical drinking to the manic-depressive constitution. Many of these cases had been called dipsomania, but, as Dr. Bailey had said, they were to be differentiated from true dipsomania with epileptoid features. One observation made by Dr. Bailey was a surprise to the speaker, viz., that a rigid pupil was of common occurrence in alcoholic psychoses. A nonreactive pupil associated with absent knee jerk, as found in one of the cases reported, would certainly raise the question of the presence of a metasyphilitic disorder and would necessitate a lumbar puncture. Dr. Kirby had rarely observed in alcoholic cases a rigid pupil that could not be explained on ground of some local eye condition. Even in Korsakoff's psychosis, where the damage to the nervous system was most severe, we did not find any impairment of the pupillary reflex. Inactivity of the pupil had, of course, been reported in epileptic and hysterical attacks as a transitory symptom.

Dr. Bailey, in closing, said that the question first came up to him regarding immobile pupils and absent knee jerks about two years ago in the person of a patient who had been markedly alcoholic all his life and was taken with rather atypical symptoms of neuritis, atypical in that the muscles involved were of the thigh and not the lower leg. This man had stiff pupils. His condition was such that it was impossible to get a satisfactory history, and the question balanced itself between alcohol and syphilis. It was for a long time in doubt. He looked up the question to see if there were any precedents, and found that Kraepelin had mentioned stiff pupil in alcoholism in his book. Bonhoeffer also mentioned it. Dr. Bailey did not advance it as a frequent symptom in such cases, but where there was a question between alcoholism and paresis, the fact that the pupil was stiff and knee jerks absent was not always final evidence of paresis. The case certainly was not paresis. His pupils now responded to light. In one case, referred to in his paper, the pupils and knee jerks both returned within a few weeks after cutting off alcohol. He was very much interested in Dr. Brooks having found a case of true melancholia with spasmodic periods of drinking. He had doubted this form of dipsomania, and he would like to ask some of the gentlemen with a much larger experience than he had had what their experience was; was it common for the melancholic states of manic depressive insanity to have periodic drinking spells? He stated in his paper that it was not, and he did not wish to state so if it was otherwise. He had never had a case of melancholia with any tendency to excessive drinking at all, except some cases of melancholia in old people when then settled down into mild dementia.

Dr. Dana said he would like to ask Dr. Bailey in this case where he found rigid pupil whether there were not symptoms of syphilis.

Dr. Bailey said there were simply evidences of peripheral neuritis.

Dr. Dana asked if Dr. Bailey had made an examination of the pupils in epileptiform attacks.

Dr. Bailey said he had seen only one case, and in that, as he remembered, the pupils responded promptly.

Contribution to the Etiology of Manic-Depressive Insanity.—This paper was read by Dr. August Hoch.

College of Physicians of Philadelphia.

At a stated meeting, held October 6, Dr. William M. Welch read "A Memoir of the Late Dr. Horace Y. Evans." Dr. George W. Norris read a paper entitled "Extrasystolic Arrhythmia Simulating Heart-block." He reported the case of an elderly man who presented arrhythmia of the heart, the pulse at times being just one-half of what it was at other times, and presenting on auscultation at such times a third beat in addition to the first and second sounds. Graphic records, however, showed that the case was in reality one of arrhythmia with extrasystole, and post-mortem ex-

amination disclosed a condition of extensive degeneration of the heart muscle, without especial involvement of the auriculoventricular connecting bundle. The abnormal pulse frequency could be induced by the administration of digitalis, by pressure on the abdomen, by physical exercise, and by other influences acting so as to cause increased arterial tension. Dr. PAUL LAZARUS of Berlin made, by invitation, some remarks on "Arteriospastic Conditions." He pointed out that in consequence of the normal overaction of the constrictor muscles of the arteries the state of vascular tone resulted, and that arterial contraction or dilation took place from the action of various irritating influences, some acting from within, others from without, or from a distance, or through reflex stimulation. He dealt with functional in contradistinction to organic disorders. The disorders comprised under these heads were numerous and included such affections as migraine, acroparesthesia, erythromelalgia, paresthetic neuralgia, Raynaud's disease, paroxysmal hemoglobinuria and hematuria, dermographisia, vasomotor ataxia, Stokes-Adams syndrome, angina pectoris and pseudoangina, intermittent claudication, sclerodactily, scleroderma, and others. The crisis of locomotor ataxia has been attributed to vasomotor spasm. He cited an instance in which long continued arterial spasm terminated in arteriosclerosis, and also a case in which, in the sequence of emotional shock, symptoms of local pallor, cyanosis, atrophy, and gangrene developed in the upper half of the body, while hyperemia and hypertrophy developed in the lower. He expressed the view that functional derangement, frequently repeatd or long continued, might readily result in anatomic change, and he pointed out that all functions is attended with vasomotor and nutritive phenomena.

Resistance of the Diphtheria Bacillus to Drying.—Francesco Valagassa has experimented on the effect of dessication on the diphtheria bacillus. He took virulent cultures and dried them in a low heat, after which he kept the dried dust in test tubes in the laboratory at an ordinary temperature for two years, cultivating the germs every two weeks. He found that they remained virulent throughout the two years. This experiment has an important hearing upon the carrying about and contagion of diphtheria in the house in which a patient is sick, and by persons who have visited and cared for the patient to persons outside the family. It shows that these germs are very tenacious of life and that they may be carried in clothing and other materials which have not been fumigated, and may remain virulent for a long time in these articles. It is also important with reference to the prevention of the disease. The use of antitoxin, while it may benefit the patient and cause a rapid cure of all symptoms, should not cause us to be careless of the disinfection and sterilization of all materials that have been in contact with him throughout any period of his sickness.—*Rivista di Clinica Pediatrica.*

Comparative Value of Operations for Retroversions and Retroflexions of the Uterus.—Maurice Bourcart, after a careful review of the various procedures that have been proposed for the radical treatment of retroversions and retroflexions, gives us the following conclusions: the operation that maintains the organ in as near a position to the normal as possible and preserves the functions is that which is best adapted to the treatment of this displacement. The question of pessaries is left aside as only palliative means of treatment. We must take account of the general condition of the patient, the abdominal equilibrium, and the various causes of displacement. From a failure to observe these things operators have failed to relieve the symptoms of the patient. The modern Alexander operation is best suited to young women who are likely to have children and to unmarried women. Ventrofixation is best suited to women who have reached the menopause or who have been sterilized by necessary operations for disease of the uterus and adnexa. It should be complementary to laparotomy for these troubles. Vaginofixation should be done in exceptional cases.—*Annales de Gynécologie et d' Obstetrique.*

Medical Items.

Contagious Diseases, Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week of October 23, 1909:

	Cases	Deaths
Tuberculosis Pulmonalis	542	145
Diphtheria	259	19
Measles	119	9
Scarlet Fever	118	3
Smallpox	—	—
Varicella	44	—
Typhoid Fever	107	25
Whooping Cough	62	4
Cerebrospinal Meningitis	3	4
Malarial Fever	—	—
Totals	1,254	209

Pathogeny of Certain Epidemics of Gastroenteritis.—Decherf calls attention to errors in feeding of the cattle used for the production of milk for feeding of infants as a cause of gastroenteritis. Aside from its chemical qualities, this milk contains biological qualities that may be injurious to young infants. The origin of epidemics of gastroenteritis is in some cases due to the feeding of the cattle on fermented or fermentible materials called pulp, derived from factories where beet sugar is made or from distilleries. Such milk contains toxins which cause an intestinal intoxication in the infants. These epidemics are best treated by the use of water diet only, and if intoxication is not too severe recovery is rapid. Babeurre is harmful in these cases, while in most cases of acute enteritis it is an intestinal antiseptic.—*Annales de Médecine et de Chirurgie Infantiles.*

Health Reports.—The following cases of and deaths from smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, Public Health and Marine-Hospital Service, during the week ended October 22, 1909:

PARASITISM AND NATURAL SELECTION.*

By R. G. ECCLES, M.D.,

BROOKLYN, NEW YORK.

"It is of interest," says Prof. Theobald Smith, "to note that civilized man who has subjugated or annihilated all species of large animals, finds the difficulty of controlling and suppressing them in inverse proportion to the size of the offending species. Many predatory and destructive insects which disturb agriculture are still at large, and many of the microscopic and ultramicrosopic organisms which cause disease baffle the scrutiny of science. With this study of microorganisms is bound up the phenomenon of parasitism, one of fundamental importance to life. Parasitism implies a continual struggle between the highest and lowest forms, and the investigation of the conditions which surround this struggle will be for some time to come the most fruitful field for research."[1] It is important that we understand the cause of this struggle in order to fully appreciate the origin, unavoidableness, and continued persistence of what we call disease. Such knowledge may evict us from the mental comfort of "a fool's paradise" but it will bring with it sane judgment on what is probably the most momentous and important problem that we must forever continue to face. "We now know," says Prof. H. E. Crampton, "that a bacillus less than 1/5000 of an inch in length multiplies under normal conditions at a rate that would cause the offspring of a single individual to fill the ocean to a depth of a mile in five days."[2] Commenting upon the same subject Prof. H. W. Conn tells us that "their minute size would make them harmless enough if it were not for an extraordinary power of multiplication. This power of growth and division is almost incredible. Some of the species that have been carefully watched under the microscope have been found under favorable conditions to grow so rapidly as to divide every half hour, or even less. The number of offspring that would result in the course of twenty-four hours at this rate is, of course, easily computed. In one day each bacterium would produce over 16,500,000 descendants, and in two days about 281,500,000,000. It has been further calculated that these 281,500,000,000 would form about a solid pint of bacteria and weigh about a pound. At the end of the third day the total descendants would amount to 47,000,000,000,000 and would weigh 16,000,000 pounds."[3] If Prof. Conn had gone on with his calculating, as it is to be hoped the reader will do, he would have shown that by thus doubling every half hour the 16,000,000 pounds would be 32,000,000 pounds in the first half hour, 64,000,000 pounds in the second half hour, 128,000,000 pounds in the third half hour, 256,000,000 pounds in two hours, 512,000,000 pounds in two and a half hours, 1,024,000,000 pounds in three hours, and thus continuing until, in a relatively small number of hours, all of the protoplasm-forming food upon our planet would be converted into bacteria. This, of course, means that our bodies and the bodies of all other living things would be consumed and changed into bacterial tissue. It is quite evident that no such result can be reached, but why? Simply because our tissues and the tissues of plants and animals refuse to be eaten up in this wholesale manner. As soon as life disappears from our bodies, or our tissues are lacerated or otherwise weakened in their resisting power, the multiplication begins. As long as life and health last our organized bodies struggle with all their power against the pressure of this aggressive proliferation. It is as certain as fate that but for the barriers that higher living forms have been able to put up against these marauding germs every other form of life but their own would be compelled to disappear from the face of the earth. Our cells must kill, inhibit, or force into starvation countless millions of them every day. It is a struggle to the death between us all the time. It is a struggle that has never for a moment ceased in countless milleniums of time. As it is there is not an available spot on or within us, where they can cling or rest, that they have not preempted. Our cells limit their freedom, as we do that of caged lions, or they would invade our circulation and make life a burden to us. Let there be a laceration, a bruise, an injury from heat, electricity, or frost, a chilling of the circulation, or any other condition that lowers our vital resistance, and their merciless proliferating begins at the expense of our being. Herbert Spencer was certainly right when he asserted that "natural selection has always been going on, is going on now, and must ever continue to go on,"[4] although he knew but little about this phase of it. In the battle with pathogenic microorganisms death is the inevitable fate of all those whose tissues are unable to beat them back and hold them at bay. Fitness is bodily resistance and only the fit are able to survive. This, too, is just as true for the parasite as it is for its host. Their power to resist us is their fitness and only the fit among them can survive. To both germ and host "the dictum of the environment is: accommodate to xyz or die in the attempt."[5] Every favorable change made by one of them must be overcome by an equally protective or a more protective change in the other. In this way adaptation is added to adaptation from generation to generation. In this way heredity heaps up the wealth of protective appliances. Here it can surely be said that,

"All of good the past hath had,
Remains to make our own time glad."

This idea was evidently in the mind of the writer of the British Encyclopedia article on "Parasitism"

*Supplementary to a paper on the same subject in the MEDICAL RECORD, July 31, 1909

when he wrote that, "It is possible that many of the most remarkable integumentary specialisations of the animal kingdom are defenses against parasites (somewhat as stings or thorns which protect foliage, or the hairs which keep ants from flowers); thus the nemocysts of coelenterates, the molluscan shell or the crustacean mail, the vigilant pedicillariae of the echinoderm, or the scales of the fish are alike largely specialized as defenses against the never-ceasing attacks of swarms of larval parasites eagerly struggling to gain entrance or footing anywhere."[6] The fact here referred to that every integument is exactly suited to protect its possessor from the kinds of parasites by which it is attacked is both interesting and important. Our skin would not properly protect a fish or an oyster nor would the coverings of fish, oyster, lobster, or snake be proper or protective coverings for us. Every kind of integument is only fit for the resistance of the enemies that its wearer meets or has met during its evolution. They have survived because of this fitness. Remove it and they would perish. They are all defenses against injury and the infections that follow injury. This process of heaping up adaptations has been going on for so immense a period of time, and in every form of living thing, that—in a sense—all are, at any given period of time, to be counted among the fit. But for incessant change we would all remain fit. It is because the respective relations between pathogenic germs and ourselves is constantly shifting that we are always slowly being forced toward the region of unfitness. No sooner have we built up a wall of defense for our blood than some microorganism varies in a way that enables it to make a breach into the same. No sooner have our cells adopted a means of poisoning or dissolving them than they have again varied in a manner that neutralizes our poisons and checks the effectiveness of our solvents. Those that do not vary thus become the tamed facultative forms that may in time become pure saprophytes. They are forced into adaptation to a new way of living. If not able to assume the new mode of life they must die. "Now we can see," says Prof. Crampton, "why adaptation is a universal characteristic of species—there are no unadapted. If such there were, they have fallen long ago and the world knows them no more. True it is that perfection is not attained by any creature, but it must establish a *modus vivendi* or it perishes."[7] As far as our structures go in the direction of perfect adaptation we are all adapted. As far as they fall short of this, because of some new shifting of the conditions of battle, they are all unadapted. Our adaptations protect us against the multitude of dangers that our forebears had to face but not against the new dangers to which they were utter strangers. "The Darwinian theory," says Prof. W. K. Brooks, "simply affirms that" our adaptations "work well enough to enable the organism to hold its own against such competitors as it has met with, but admits the possibility of indefinite improvement."[8]

We are never free from the danger of infection. Our oldest, most subtle, and worst enemies—disease germs—threaten health and life always and at many points. Our skins, our mouths, our alimentary tracts, our food, our water, and even the air we breathe constantly contain microorganisms of varying degrees of virulence. They never leave us. Streptococci, staphylococci, pyogenic cocci constantly lurk in the canals of our hair follicles, seek favorable opportunities for proliferation within the sebaceous glands, and hide in every crevice of the epidermis. "We carry in our skin surfaces constantly," says Dr. Simon Flexnor, "the germs of suppuration."[9] Once let them gain the slightest advantage over our cells and the result will be pimples, boils, carbuncles, abscesses, erysipelas, or general cocci infection. Against them heredity has accumulated an exceedingly interesting set of adaptations to which familiarity has bred indifference. Every one of them is, or has been, life saving. They are, therefore, of a kind that are said by biologists to be of "selective value." A remarkable feature of them is that their selective value is entirely concerned in protecting us from pathogenic microorganisms. The skin, in all of its functions, seems to be chiefly—or wholly—a defense against infection. To the Darwinian this can only mean that its entire structure is an accumulation of myriads of surviving fitnesses in its wars against disease. If Natural Selection is true we could never have had a skin like that which we now possess had it not been for disease as the selector. If the reader will carefully scan the following list of protective appliances which the possession of our present integument supplies, my meaning will, perhaps, be clearer. (a) It is constantly shedding its surface cells and thus ridding the body of bacteria. (b) It is covered with hard, horn-like cells impenetrable to bacteria and of inferior nutritive value for them. (c) It thickens by wear and thus lessens our danger from a germ invasion when such an invasion would otherwise be unavoidable. (d) It lubricates and moistens itself thus preventing the formation of cracks and fissures through which bacteria could enter. (e) Its mechanism for the control of internal temperature maintains the general resisting power of the body against disease. (f) The flow of blood, in puncture or cut, washes out the wound and rids it of many bacteria. (g) The clotting of the blood seals up the injury from further infection. (h) It gives prompt warning of danger from infection by the production of intense pain the instant that it is punctured or cut. (i) It informs us of movements upon its surface, on the part of marauding insects and proliferating germs, so that we are often able to avoid inoculations with disease germs by scratching off the moving objects. (j) It supplies us with broad nails to enable us to evict these moving things. (k) It provides a reflex mechanism that by the sensation of tickle must have saved primitive man from many wounds and many infections. (l) It supplies another reflex mechanism by which to protect the delicate eye from injury and infection through winking. (m) The touch-spots, by their curious distribution, must have saved primitive man from many attacks of infective disease. (n) The heat and cold spots supply warnings from dangers that threaten vital resistance. (o) Our practically hairless skins lessen fatality during attacks of exanthematous diseases.

As can be seen, this entire list of defenses is for our defense against pathogenic microorganisms. If we are not the selected survivors of creatures that once had a different kind of skin we might as well have been, so far as any reasonable explanation of the facts is concerned. The germs are here and, from all appearances, have always been here. The selecting of fitnesses is now and, so far as can be seen, has always been going on. Geologists tell us that there has been ample time for a countless number of fitnesses to have piled up to make us what we are. Every peculiarity that distinguishes our skin from that of a fish, amphibian, or reptile seems to

be exactly such as we would gain by the aid of time, selection and germs. Well may we say with Prof. Poulton that, "When a naturalist has found the formula 'if Natural Selection be true, so and so ought to happen,' the safest of all guides into the unknown, when it has brought home success many times and in many different directions, when he knows that many other workers in other fields of biological inquiry have had a similar experience, he gradually comes to feel a profound confidence in the permanent truth and the far-reaching importance of the great theory which has served him so well."[11] Why should he not acquire such faith? For half a century Darwin's theory has been the same to biologists, of every stripe, as the mariner's compass has been to the captains who have guided their ships by its aid. The evidence in favor of natural selection is cumulative. Its apparent failures, one by one disappear before advancing knowledge. With Prof. Conn we should be willing to say "that inasmuch as the law of natural selection is a universal force which all admit, while all other forces of evolution are yet in dispute, and inasmuch as many seemingly useless organs have been shown to be of use, it is perfectly legitimate to claim that when we come to understand them, we shall find that all characters are of value, and that the principle of survival of the fittest has been concerned in the development of them all."[12] It is a singular fact that a very large number of the most apparently staggering examples of anti-Darwinian objections resolve themselves into adaptations against disease. Some of them will appear as we progress in the presentation of the data of this paper while others will be reserved for some future article. In pre-bacteriological times they appeared to be utterly irreconcilable with natural selection. Indeed, as we shall see, they baffled completely the ingenuity of Spencer, Darwin, and Wallace. Only when viewed from the standpoint of modern pathology is it possible to see that they are Darwinian. One of the first objections urged against natural selection was made by Mivart when he declared that, "We cannot believe that the first minute beginnings of adaptation are valuable enough to be preservative."[13] In the battle against pathogenic microorganisms the most infinitesimal additions or subtractions can tip the delicately poised scale toward survival or toward death. When life is already trembling in the balance differences of inconceivable minuteness may register the decree of fate. Prof. Conn's question—Can it be imagined that the lengthening of the tail by a couple of inches can be of selective value?—must be answered in the affirmative now that we know something about tsetse flies and trypanosomes. When Mivart penned the words we have quoted no one knew of the subtle but telling influence that disease has upon natural selection. When we have learned more upon this subject than we yet know it will be time enough to inquire about how minute the additions to adaptations must be in order to become of selective value. One tenth of an inch added to the length of a tail, by enabling its possessor to reach an otherwise unprotected tenth of an inch of its body surface, might, other things being equal, supply the very fitness needed for survival from an attack of nagana. Who can say how slight a change in the chemical structure of the corneal cells of our skin would enable bacteria to penetrate and flourish upon them? Who can say how slight an alteration in the desquamating power of our skin would enable proliferating cocci to infect the interiors of our bodies?

"The epidermic layer," says Metschnikoff, quoting Sabourand, "sets up a defense by the production and expulsion of corneal cells. In the normal course of the life of the epidermis, the cells of the deeper layers, coming to the surface, become exfoliated and thrown off. 'There is thus produced, a continual exfoliation of the dead layers, and a continual eviction of such microorganisms as are living on them. The epidermis is dense and its cells have a hard envelope; the microorganism is not endowed with motion, or at least not with sufficient to be of service in effecting an entrance. It can only penetrate the epidermis by a multiplying *in situ*, a microorganism originates alongside another, another in front of it, and in front of this again others. In this way they burrow between the opposed cells just as a root penetrates into the ground; so great is the resistance of the horny cells that we never find any microorganisms within them, but between them only.' The epidermic cells, containing microorganisms, exfoliate, and the skin is thus ridded of them. Frequently the process, as it goes on constantly and slowly, is invisible; but often, on the other hand, it becomes exaggerated and manifests itself in the form of a cuticular desquamation which leads to the elimination of a large number of microorganisms."[13] If such patent fitnesses are not the accumulated capital of millenniums of selection then to what earthly cause shall we accredit them? Weismann's statement regarding the adaptations of mimicry applies with equal aptness here. "There is only one explanation possible," he says, "for such patent adaptations and that is selection. What is more, no other natural way of their originating is conceivable, for we have no right to assume teleological forces in the domain of natural phenomena."[14] Consider for a moment that peculiar power which the skin possesses of thickening by work or wear. Where among all material things can its like be found? The hardest steel and the most dense platinum can be thinned down to nothingness by the same kind of treatment. Continuous attrition produces a result that is exceedingly anomalous in the case of living integuments. It is particularly evident in the palms of the hands and soles of the feet, places where such thickening is most needed. Use and wear mean increased exposure to conditions favorable to injury or puncture. Injury or puncture mean increased danger of infection. The thickening is an adaptation against disease. During millions of generations of such exposure the absence of such thickening must have meant extinction. Only those animals whose skins varied in the right direction could have survived. Prof. T. H. Morgan tells us that "We may regard this as a general property of the skin, which is present even in those parts where, under ordinary circumstances, it can rarely or never be brought into use."[15] While this is quite true of modern man it was not so of primitive man, nor is it now so of simians, or lemurs. In the latter cases —and they are types of those animals which, according to the theory of natural selection, preceded us— all parts of their bodies must be subjected to intermittent wear, owing to their arboreal life. Pushing through dense jungles, clambering for nuts among interlocked boughs of trees, with scratchings and rubbings in order to get rid of adhering parasites or vermin, could hardly be accomplished without daily and hourly bringing this property into requisition as a life saver. But thickening without pliability would have resulted in cracking, so we find that the palms and soles are more liberally sup-

plied with sudorific glands than is any other part of the body. "As long as the uncracked epidermis only is presented to bacteria," says Prof. Dearborn, "there is relatively little danger of infection."[16] Through the sweat glands these parts are kept sufficiently moist and oily to maintain their normal condition under such strain as they are constantly subjected to. Unlike the rest of the body they are not supplied with sebaceous glands. The absence of hair makes these unnecessary and the uses to which hands and feet were put by simians would have made oil lubrication rather dangerous. The avoidance of drying, cracking, and puncture are sufficiently provided against without them. Still another menace was avoided by an increase in the number of sweat glands and the absence of sebaceous glands. Work makes heat and a thickened skin with increased heat added needed a mechanism to balance this danger from an accumulation of temperature. The chief function of the sudorific glands for the body is that of keeping down temperature. But for them every effort we made in work or exercise would raise the body heat to the danger point. "Krause estimates that their total number for the whole cutaneous surface is about two millions."[17] The evaporation of the excreted moisture carries off the heat. Too much evaporation, however, would lower the temperature to an extent that would be equally dangerous and so we find that there is a nervous mechanism for its regulation. Dilation of the splanchnic vascular areas or constriction of the cutaneous vascular areas lessens the flow of blood through the skin and raises the temperature again. The lungs also help us in the removal of surplus heat.[18] The conditions of gland supply on the palms and soles is reversed in the case of the glans penis and prepuce. Here there is an absence of sudorific glands and a supply of a special kind of sebaceous glands—the glands of Tyson.[19] Exudation of moisture in this region would encourage bacterial proliferation, while absence of oleaginous material would cause drying and cracking. Under the arms, where sudorific glands abound and where two surfaces of skin might touch and harbor proliferating bacteria, there is a growth of hair that keeps the surfaces apart and thus avoids this danger. All over the body, except in the places named, sebaceous glands abound. Their secretion keeps the hairs from becoming brittle and forms a thin protecting layer over the surface of the skin. "By means of this secretion the skin is oiled and is thereby rendered soft, pliant, and almost impervious to water."[20] Its lack of conductivity of heat and electricity also prevent too rapid changes in our store of these. As regards the insulation which it provides too little is known. Here physiology has a much neglected field to cultivate. Pathology, too, should try and discover the relations that exist between electricity and constitutional resistance to disease. It is absurd to suppose that so potent an agent, and so ubiquitous an agent, should not have an effect upon disease and survival almost, or quite, as great as that of temperature. Our skins are non-conductors, the sebaceous secretion is a non-conductor, and our hair and nails are likewise non-conductors. Such an adaptation cannot be useless and yet no one can say, at present, what its use is.

Wounds that penetrate the skin produce bleeding. A slight flow of blood from a wound is beneficial, an excessive flow fatal. In the vast majority of injuries to the skin the flow is only sufficient to lessen the danger from microorganisms that were forced in when the damage occurred. When it has accomplished this result it spontaneously ceases. Great wounds during feral and savage life could not be of selective character because, when produced, the vigilant enemy was ready to eat up the wounded prey. Accidental wounds of a serious character must have been extremely rare. There were no blasting explosions, no railway wrecks, no manglings by cannon, and none of the numerous sources of severe injury that are the associates of civilized life. Natural selection has, therefore, never had a sufficient opportunity to supply us with spontaneous closure of severed large arteries. What it has done, for us in the case of minor injuries is really wonderful. Familiarity blinds us to the astonishing features of this miracle. "Outside the body," says Dr. B. L. Abrahams, in the *Lancet*, when commenting upon the coagulability of the blood, "this is a normal process, having for its object the closure of wounds; inside the vessels it is abnormal and fraught with great danger. It is to the advantage of the body to favor the one and to hinder the other; so we find intravascular clotting difficult to produce but extravascular difficult to hinder."[21] Could phenomenon be more startling than this? If told of it for the first time, instead of seeing it as a common event of life, we would promptly declare it to be a fairy tale. Where else can we discover so miraculous a contradiction of properties in one and the same substance? It clots into a jelly exactly when it is of a benefit to us that it should do so. It flows like water when if it should do otherwise we would surely die. In veins and arteries it is a free flowing liquid but the moment it touches the edge of a wound that needs healing, through its agency, that moment it ceases to flow and plugs up the damaged spot against invading bacteria. Reverse this condition for an instant and death would reign supreme through all the earth. How happen we to have blood that clots at all? How came the clotting to occur with such exact precision as to place and time of our requirements? Biological chemistry can tell us much regarding the chemical conditions responsible for the clotting but can cast no light on the weird strangeness of the dual fitness. Ask the chemist to explain how the adjustment came to exist that made the blood clot outside the veins instead of inside of them and he will be dumb. Nothing but the law of natural selection can illuminate this mysterious condition of things. With the phylogenetic development of living forms having blood and blood-vessels these properties must have been slowly gained by the selection of variations that led to this result. It is evident, too, that other protective devices came into being along with this and in the same manner. Before the most minute arteriole can be severed the watchful nerves give out a cry of pain. Not even a needle point can break the merest dot of the skin's continuity without this danger alarm being felt. We are thus compelled to guard our epidermis from thorns and thistles, insect bites and abrasions, cuts and tears, at every appearance of such a danger. Why? It is not because such slight cuts are, in themselves, such serious things. It is because they act as portals of infection and thus have a life and death value for the sufferer. It is because ages of selection have most likely wiped out every creature whose skin did not keep becoming more and more sensitive and painful to such injuries. Nor was this adequate. The danger from infection in this way is so great that the pain had to be anticipated by another prior annoying sensa-

tion. The crawling vermin and the proliferating bacteria were made to add this other warning as an anticipation of possible puncture. Our sense of comfort was, therefore, disturbed by a feeling of itchiness. This compelled scratching and scratching dislodged mites, pediculi, fleas, bugs, chigoes, bacteria, and other such marauders. Our thick-skinned, hair-covered lemurian progenitors did their scratching with claw-like nails. Our thin and hairless skins would be constantly lacerated by claws. Wide nails could not get past their matted hair to do successful scratching. We do not require claws to get through the hair upon our bodies. The fitness of wide nails must have come with our delicate skins. Any other kind of nail for us would increase the death rate by increasing infection. Our present exceedingly low death rate from infection, through scratching, starting erysipelas or general pyemia, must be the last remnant of what was once a very high one. From the time that our forebears first got their thin skins to the time that the claw-nails widened out into our present pattern it is highly probable that the deaths among them, from this cause, must have been very great. Itching as a fitness against infection must be as old as, or older than, claws. It was evidently of little or no use as a warning against the light touch of larger carniverous enemies for still another sensation was evolved by natural selection to forewarn of these. In order to be sure that their prey is alive and not the carcass of an animal dead of some contagious disease all ferocious beasts seem to have a habit of smelling and lightly touching bodies that they happen upon without having killed. On discovering that they are edible a vital part is seized and the resting or sleeping prey despatched immediately. If the odor is repulsive it means danger to the carniverous animal and it goes its way without the hoped-for feast. Primitive man probably sought protection from lions, tigers, bears, wolves, and the like, by sleeping in holes or caves. Often these were small and provided scant safety. His feet, with the soles exposed, would reach to the narrow passageway. Without the warning supplied by the light touch of the enemy's snout or paws he would have been seized, pulled out, and devoured. Only such of them as developed a sense of tickle, that compelled a sudden withdrawal of the feet, could be saved. When forced to sleep under a bush, or in other location where almost complete exposure was unavoidable, strength and adroitness alone could save. In such cases ticklishness would save many lives by occurring on parts of the body that most needed defense. These, in fact, are found to be the very parts that respond most promptly to tickling, not only in man but in many other animals. "A young ape or dog," says Dr. Louis Robinson, "which, in the innumerable sham fights of its youth, learns to defend the axillæ, where a single bite might sever the axillary artery; the neck, with the carotids and windpipe just under the surface; the flanks, and borders of the ribs, where a comparatively slight tear lays open the abdominal cavity; and the groin, where the great femoral vessels lie close to the skin, would, without doubt, be vastly better equipped for the fierce combats for supremacy in after-life than an animal which had not undergone the same elaborate training. * * * An inquiry into the special warlike tactics of some other creatures which show a marked degree of ticklishness gives our argument additional support. All the *Canidæ* and *Felidæ* habitually attack the throat; and, in the romps of young puppies and lion cubs, it seems to be the chief end of the game to 'get in' at this spot. Now, the throat and adjoining parts are in these animals markedly the most ticklish regions. There are reasons for thinking that among ourang-outangs the same spot is more often assailed in actual warfare than is the case with the chimpanzees, and a young ourang appeared to be much more ticklish in the neck than a young chimpanzee."[22] While the reflex movements due to ticklishness are not direct selections by disease they appear to be indirectly such. The habits of the carnivoræ that lead to the touching and smelling of bodies, in order to make sure that they are not dead and decayed, have all the appearance of being directly due to selection. Some carniverous animals are less particular than others regarding what they eat, and mere decomposition does not stay their appetites; but there are reasons for believing that even these have a choice and will not eat everything in the shape of food they happen upon. The one pronounced reflex movement that has every appearance of having been the direct result of natural selection is that of winking by the eyelids. Here we have an adaptation that is of direct and decided benefit in that it saves the delicate tissues of the eyes from injury and consequent infection. But for the prompt closing down of the lids upon the mere suggestion of approaching danger many eyes would be destroyed and many lives lost by the infections that would follow contact of solid bodies therewith. Any change leading toward the loss of this power would, in time, lead to the extermination of the inheritance line of those losing it. All past changes that led toward its increased efficacy led to the survival of the race through the changed ones. Time heaped up the fitnesses until they reached their present delicacy and efficiency.

The distribution of the touch-spots over our bodies has, for years, been a most puzzling problem to physiologists and a bone of contention between Lamarckians and Neo-Darwinians. Strange to say, Herbert Spencer raised this as his most powerful evidence against Weismann in the fight about acquired characters. Had Spencer realized the important part that disease plays in the survival of the fittest it is hardly likely that he would have given such prominence to this point in his article upon "The Inadequacy of 'Natural Selection.'" For so strong a believer in selection to give over to his enemies so remarkable a proof of the truth of that principle shows how the most powerful of intellects can go astray when the data is inadequate. He surrendered a powerful fort to the enemy in an effort at suppressing what he thought was philosophical rebellion. The new facts of bacteriology and of protozoology would have saved him from so serious a lapse had he known the last words of these at the time he wrote the article referred to. Referring to Weber's experiments on the sensitiveness to touch of compass points, as displayed by various parts of the body, Spencer says: "As thus measured, the end of the forefinger has thirty times the actual discriminativeness which the middle of the back has. Between these extremes he found gradations." He refers to other contrasts of the same kind and then asks: "What is the meaning of these differences? How in the course of evolution have they been established? If 'natural selection' or survival of the fittest is the assigned cause, then it is required to show in what way each of these degrees of endowment has advantaged the possessor to such extent that

not infrequently life has been directly or indirectly preserved by it." In order to emphasize his doubt of there being selective value in the peculiar method in which these spots are distributed he declares that, "If the cause alleged is natural selection, then it is necessary to show that the greater degree of the power possessed by this part than by that, has not only conducted to the maintenance of life, but has conduced so much that an individual in whom a variation had produced better adjustment to needs, thereby maintained life when some others lost it; and that among the descendants inheriting this variation, there was a derived advantage such as enabled them to multiply more than the descendants of individuals not possessing it. Can this or anything like this be shown?" For the purpose of strengthening his objection he next asks: "How about the back of the trunk and its face? Is any advantage derived from possession of greater tactual discriminativeness by the last than by the first? The tip of the nose has more than three times the power of distinguishing relative positions which the lower part of the forehead has. Can this greater power be shown to have any advantage? The back of the hand has scarcely more discriminative ability than the crown of the head, and has only one fourteenth that which the finger tip has. Why is this? Advantage might occasionally be derived if the back of the hand could tell us more than it does about the shapes of the surfaces touched. Why should the thigh near the knee be twice as perceptive as the middle of the thigh? And, last of all, why should the middle of the forearm, middle of the thigh, middle of the back of the neck, and middle of the back, all stand on the lowest level, as having but one thirtieth of the perceptive power which the tip of the forefinger has? In order to clinch the argument and, as he seemed to suppose, make it wholly unassailable he says: "Doubtless some of those who remember Weber's results, have had on the tip of the tongue the argument derived from the tip of the tongue. This part exceeds all other parts in power of tactual discrimination, doubling, in that respect, the power of the forefinger-tip. It can distinguish points that are only one twenty-fourth of an inch apart. Why this unparalleled perceptiveness? If survival of the fittest be the ascribed cause, then it has to be shown what the advantages achieved have been; and, further, that those advantages have been sufficiently great to have had effects on the maintenance of life."[23] Prof. T. H. Morgan, who believes in some unknown power or law lying behind variations and that fashion's adaptations *en bloc*, agrees with the destructive part of this criticism. In the apparent leaps of nature known as mutations he thinks he can see an influence that lessens the responsibility of natural selection and, perhaps, supersedes it. To this he attributes the touch-spot arrangement. Spencer credits it to the Lamarckian principle of use. The parts that are used most develop the most spots. Unfortunately for Spencer's explanation no such distribution exists and Prof. Morgan takes pride in pointing this out. He has as little use for Spencer's Lamarckian theory as he has for Darwin's. He first shows that we have not a particle of evidence that the using of a part can increase the number of sense organs. He shows that, according to the Spencer-Lamarck theory, the lower part of the forearm should have more touch-spots than the eyelids because the forearm at that point is touched much more frequently than the eyelid. The reverse of Spencer's contention is true. The forehead being touched more frequently than the eyelid should also have more, while, in fact, it has fewer. The knee, that is subject to touch and pressure much more frequently than forehead, forearm, or eyelid, has fewer touch spots than any of the latter. It, therefore, demonstrates the falsity of Spencer's explanation.[24] But for the fact that Prof. Morgan's own theory is one of as complete mystery as any of the miracles of antiquity, critics might get a chance to make a shy at it. To try to riddle a theory that acknowledges its own genealogy to be unknown would be as futile as firing a gun at an immaterial ghost. The wonder is as to why neither Mr. Spencer nor Prof. Morgan tried to think of the spots in the order of their frequency, beginning with the most frequent, and paralleled that order by any sort of theoretic danger By the law of natural selection the greater the frequency the greater must have been the danger and the less the frequency the less the danger. Belfield-Lefevre has shown that "those portions of the skin where the touch is most acute, and where two points of contact are perceptible at slight distances, are," other things being equal, "those which estimate most correctly the degree of pressure."[25] This function of estimating pressure in the ratio of the number of the touch spots is important. Foster tells us that "The more mobile parts or those which execute the widest movements most easily and frequently, such as the hands and lips, are those by which we can thus discriminate sensations most readily."[26] This comment follows immediately after the following table of Weber's findings:

Tip of tongue	1.1	mm.
Palm of terminal phalanx of finger	2.2	"
Palm of second phalanx of finger	4.4	"
Tip of nose	6.6	"
White part of lips	8.8	"
Back of second phalanx of finger	11.1	"
Skin over malar bone	15.4	"
Back of hand	29.8	"
Forearm	39.6	"
Sternum	44.0	"
Back	66.0	"

If the reader will now join with me in trying to put two and two together in this physiological puzzle we may be able to solve it, even if it did defy authorities as great as Herbert Spencer and Prof. Morgan. Let us stick to Darwin's method—the method of Zadig, according to Prof. Huxley.[27] If natural selection is true the center of danger in reference to these touch spots must be the tongue. It exceeds all other parts of the body in its sensitiveness. The second point of greatest danger to life must have been the palm of the terminal phalanx of the finger. What has the tip of the finger got to do with the tongue? Why does it come next to the tongue as a cause of danger to the life of a man? Do these two ever come together as a source of possible danger? Let us now compare the extremes. The tongue is 66 times more sensitive than the back and the end of the finger is 33 times more sensitive than the same region. Does the back of man, monkey, or lemur ever reach the tongue? But Foster says that "the more mobile parts" are the parts of sensitiveness, and, therefore, according to any selection explanation, all danger centers around the chances that a part has of reaching the tongue. But the tongue is only reached in this way when licking has to be done or when something upon the part has a chance to reach the tongue. The less the chance of anything reaching the tongue, it would thus appear, the less

must have been the danger. That this is *most emphatically* the case is seen in what is a decided exception to Prof. Foster's rule. The back of the hand is nearly 15 times less sensitive than the palm of the terminal phalanx and yet—strange to say—the back of the hand *can reach the tongue* just as easily as the palm can. But does it in the usual movements of an animal reach it with anything like the same frequency as the palm? In animals that feed themselves and take their drink by the aid of hands it most assuredly does not. As the touch-spots are a heritage from our hairy ancestors, and as these ancestors were not overcleanly, accumulations of infected material must often have stuck to their hairy coverings. When the mass got large enough to be felt as a tangible body it would become an annoyance to be removed by picking it away, shaking it off, or brushing it off against shrubbery. To make sure that it was not something good to eat it would be tested by taste and smell. In places most easily reached by the tips of the fingers the danger would be the greatest of its reaching the tongue. In clinging to the teeth its danger would be exceedingly great. There it would find warmth and moisture—the ideal conditions for multiplication of disease germs into a dangerous dose. Without keen sensitiveness of the tongue to minute particles of infective matter clinging to the teeth there would be no incentive to having a clean mouth. Liberally as we are endowed our sensitiveness to touch by our tongues does not discriminate with as much keenness as would be to our advantage. Health is often impaired by dirty teeth. Imagine what it would be but for the delicacy of touch on the part of the tips of our tongues. The touch spots, as distributed over the body, diminish in numbers over any given area inversely as the danger was from infection among our hairy ancestors. What, if not natural selection, could ever have given us any such distribution? That natural selection could and would have brought it about under such conditions seems a perfectly fair inference. The mouth is the portal of entry of fatal disease germs, the fingers by carrying food to the mouth carried these germs and the numbers carried were in proportion to the dirtiness of parts in relation to the ease with which the mouth could be reached by such dirt. The more sensitive natural selection left a part the more the danger subsided from that part. The less the danger of infecting the mouth by any part the less intense was the play of natural selection through that part.

The distribution of the heat and cold spots of the body is so difficult to determine with any great degree of accuracy that experimenters differ materially in their results. The sensations vary with the varying temperatures of the skin itself. To attempt to discuss the cause of a distribution that is known only in a rough way would, obviously, be futile. Prof. Morgan throws this down as a gauntlet for either Darwinians or Lamarckians to pick up, but he takes very good care not to offer any explanation of his own.[28] As the cold spots are more numerous than the warm ones we can infer, from a Darwinian standpoint, that primitive man suffered more from cold than he did from heat. The fact that the sensation of cold occurs immediately and that of heat gradually is further evidence of the greater selective value of cold.[29] The mucous membranes have poorly developed temperature sense as compared with the skin, another condition that agrees with the requirements of natural selection.[30] The entrance portals to mucous membranes maintain the cutaneous function for heat and cold.[31] This is decidedly in favor of natural selection. It protects the interiors by a guard at the door. This guard, strange to say, is epiblastic in origin and is, therefore, really a part of the skin, although appearing to be a mucous membrane.

Darwin, in his "Descent of Man," tells us that, "From the presence of the wooly hair or lanugo on the human fetus, and of rudimentary hairs scattered over the body during maturity, we may infer that man is descended from some animal which was born hairy and remained so during life. The loss of hair is an inconvenience and probably an injury to man, even in a hot climate, for he is thus exposed to sudden chills, especially during wet weather. As Mr. Wallace remarks, the natives in all countries are glad to protect their naked backs and shoulders with some slight covering. No one supposes that the nakedness of the skin is of any direct advantage to man, so that his body cannot have been divested of hair through natural selection. Nor have we any grounds for believing, as shown in a former chapter, that this can be due to the direct action of the conditions to which man has long been exposed, or that it is the result of correlated development." On the same page he adds a note giving the following as the views of Mr. Wallace upon this subject: "Mr. Wallace believes 'that some intelligent power has guided or determined the development of man,' and he considers the hairless condition of the skin as coming under this head. The Rev. T. R. Stebbing, in commenting on this view remarks that, had Mr. Wallace employed his usual ingenuity on the question of man's hairless skin, he might have seen the possibility of its selection through its superior beauty or the health attached to superior cleanliness. At any rate, it is surprising that he should picture to himself a superior intelligence plucking the hair from the backs of savage men (to whom, according to his own account, it would have been useful and beneficial), in order that the descendants of the poor shorn wretches might, after many deaths from cold and damp in the course of many generations, have been forced to raise themselves in the scale of civilization through the practice of various arts, in the manner indicated by Mr. Wallace."[32] The explanation which Mr. Darwin himself offers is that of sexual selection. It is exceedingly questionable whether a female anthropoid ape would deem hairlessness beautiful and sufficiently so as to be willing to desert all males with a covering of the kind that was to them "fashionable." In such matters habit constitutes the criterion of beauty. Esthetics deal with harmony or symmetry. The intense dislike that we all possess against being odd, eccentric, or unlike others, is not due to any sense of beauty but to habit. It is a kind of conservatism. For a hairy member of a hairy race to vary toward unhairiness would, probably, be deemed the reverse of beautiful. If the hair should disappear asymmetrically it would be looked upon as hideous, and any member of such a community changing in this way would be considered a freak to be avoided. Among negroes, as Darwin tells us, the black, thick-lipped man is chosen as the beautiful man. The blacker he is the more beautiful he is thought to be. The negro's sense of symmetry cannot differ much from our own, but his race habits, in this particular, are quite unlike ours. Had either Darwin or Wallace known of the intense struggle for existence that is going on between microorganisms and the higher forms, it is hardly likely that they would have surrendered to

the enemy in the way they did. The problem, owing to the lack of knowledge of their time, was absolutely irreconcilable with those forces of natural selection known to them. Being unable to defend the true explanation they sought out makeshifts, and as a result none of the great leaders could agree among themselves. They were completely baffled by the situation, and what was really a remarkable adaptation for saving life was looked upon by them as a maladaptation due to some other cause than a survival of fitness. Besides, there are adaptations for the survival of the microorganisms of disease that are just as important for them as ours are for us. We have no monopoly of acquiring fitnesses. Nature is as careful of the microbe as of man. Both are subject to the same law.

Prof. Theobald Smith tells us that "The parasite must find an unguarded entry or one which yields readily to its efforts. It must have a means of defense within the body, and it must finally reach the exterior to enter a fresh subject. * * * In that exquisitely parasitic, highly specialized group of microorganisms producing the eruptive diseases the final process is carried on in the skin. In these diseases the mechanism of escape is the most perfect."[33] It is quite evident that this "most perfect" mechanism of escape is of supreme importance to the germ. What about its relation to us? If the germs found their escape barred by some great difficulty, would it not seem to be to the benefit of both to have it removed? If certain death faced us through keeping the germs within us, would it not be a decided advantage for all who were attacked to have as easy a method as possible of getting rid of them? This highly specialized group get out of us by way of the skin. If we must harbor them, is it not best that the skin lets them get out with the least possible resistance which would, naturally, mean the least possible damage to ourselves? Our thin and hairless skin lets them out easily, but what about the hairy skins of our hypothetical ancestors? Before these microorganisms were quite as highly specialized as they now are how did they and their hosts fare? Let us see how we fare even now after generations of selection. In one of these diseases, dermatitis exfoliativa, "the eruption begins in one or more localities, most frequently on the extremities, the face, or scalp, with diffuse erythematous or papular patches. * * * After three to eight days there follows a stage of exudation and desquamation, lasting from three to eight weeks. By the confluence of the original patches a large portion of the entire body presents a crimson surface of thickened and indurated skin, continually shedding scales or flakes of epidermis of various sizes, two or three pints sometimes being collected in twenty-four hours. * * * After a certain time the inflammation subsided, the skin still remaining thickened, with a brown, polished appearance, sometimes with painful fissures. The hair and the nails were invariably lost, and did not grow again for several months. * * * Relapses were a common feature, as many as nine having been observed in one case. Aggravated symptoms from the alimentary tract, albuminuria (in about 50 per cent. of the cases), weakness of the heart, lung troubles, or the marasmus, brought on a fatal result in about one-tenth of the cases."[34] Try and picture such a disease as this getting a start among hairy creatures such as the original progenitor of man was. What havoc it would produce among them. The pulling out of the hairs would necessarily add to the mortality by adding to the number of suppurating sores containing the germs of the disease or by terminal infections due to streptococci. The so-called "mange" cannot approach it in severity. Destruction of life, at first excessive, would gradually subside as immunity was acquired. Since both males and females, in great numbers, could be attacked in an epidemic of this kind, it is quite clear that there would be intermarriages of the recovered ones. *Any variations in the germ and sperm plasm would be of a somewhat common character, and the intermarriages would intensify the same and give us mutations.* As the disease is a lingering one the sufferers from it would be the "lepers" of the "society" of that time. It is more than likely that they would be avoided as dangerous, and so compelled to seek homes away from the rest of their race. With so severe a disease natural selection would, necessarily, eliminate all of those with the heaviest hair first and then keep lessening the hairy covering by preserving those whose cases were least severe—those most nearly hairless. In the quadrumana "the hair is always longer or more dense along the spine or middle of the back from the nape to the tail, often rising into a crest of hair or bristles on the ridge of the back," and, "as this character prevails through the entire series of the mammalia, from the marsupials to the quadrumana," we can see in this exactly how the hair "has disappeared more completely from the back than from any other part of the body."[35] These are the facts that puzzled Mr. Wallace and caused him to say that, "It seems to me, then, to be absolutely certain that 'Natural Selection' could not have produced man's hairless body by the accumulation of variations from a hairy ancestor."[36] The long, dense hair of the back and spine would create the most dangerous lesions during desquamation and so kill off most rapidly those that failed to vary in the direction of less hair, shorter hair, and less coarse hair. Woman is less hairy than man. While caring for the ailing, and nursing her children in dark caves or huts, she would be far more constantly in contact with the desquamated skin and the germ-discharging suppurating sores. Her dosage would be larger and she would be longer subjected to the same. While she would be eating stored food exposed to the pus discharges and exfoliated particles of skin he would be using fresh food from forest or field. In these conditions we likewise can see a possible explanation for the existence of that form of the disease known as dermatitis exfoliativa neonatorum.[37] Natural selection would be less severe on infants because of the less coarse character of their hair. Their immunity would, therefore, be slower in reaching completeness than in the case of the mothers. Generations of cultivation confined to babies would tend to produce a strain particularly adapted to them. Women are most immune, as would be expected from the complete way the disease must have acted upon them. The various types of this class of diseases behave exactly as if due to different strains of an originally identical kind of germ. Our lack of hair, and particularly its complete absence from the spine, woman's hairlessness and the exposure she would have had, man's present greater susceptibility to the disease, and the imperative deduction of natural selection from this viewpoint, if all mere coincidences, certainly are extraordinary ones. Quite naturally no amount of evidence could sway those who would call this a "disgusting" or a "disagreeable" conception of man's origin. Where feeling is placed in advance of fact,

fact must give way every time. It has ever been thus. The modern Nathaniels are in no way different from the ancient ones, and so they continue to ask, "Can there any good thing come out of Nazareth?"

THE ACETONE TREATMENT OF INOPERABLE CARCINOMA.

By D. W. TOVEY, M.D.,

NEW YORK.

LECTURER ON GYNECOLOGY AT THE N. Y. POLYCLINIC; ASST. GYNECOLOGIST TO N. Y. POLYCLINIC HOSPITAL; GYNECOLOGIST TO HARLEM HOSPITAL AND DISPENSARY; FELLOW OF THE N. Y. ACADEMY OF MEDICINE.

Gellhorn of St. Louis published his first paper on the treatment of inoperable carcinoma of the uterus by acetone, in the *Journal of the American Medical Association* of April 22, 1907.

At that time we had in the New York Polyclinic Hospital, in the service of Dr. Brooks H. Wells, with whom I am there associated, a patient with advanced cancer of the cervix. This woman in consequence of the fetor, sepsis, pain, and hemorrhage incident to her disease was in a very miserable weak condition and had been brought into the hospital on a stretcher. Acetone was used in this case with most gratifying results, the fetor, sepsis, and hemorrhage being relieved so that the woman gained rapidly in strength, weight, and color, and after five weeks was able to return to her home on foot. We have used the acetone since in fifteen cases with very satisfactory results.

Favorable reports on the use of acetone have been published by Polano of Wurzburg, Hëckel of Greifswald, Sémon of Danzig, Dorset & Taussig of St. Louis, and Mair & Fisher of Philadelphia. As I have been unable to find anyone in New York who has published any report of its use, I wish to call your attention to its value and to the indications and method of its use.

Patients with inoperable cancer have derived but little benefit from the remedial agents mentioned in literature. Thyroid feeding, trypsin, calcium carbide, electricity, the cancorin of Adanikrewicz, injections of various sera, or of irritating substances such as alcohol, acetic acid, corrosive sublimate, methyl violet, venom of cobra di capello, oil of turpentine, and arsenious acid. With the exception of the Roentgen rays and trypsin, which aspired to radical cure, all of these modes of treatment merely aim at making the patient's life endurable as long as it lasts.

The primary objects were and still are to reduce the weakening hemorrhages, lessen the septic absorption, and to check the intolerable stench of the discharge. Kuestner and Gottschalk devised an artificial occlusion of the vagina as a last though but temporary resort. The distressing odor, which really constitutes the most formidable symptom of the disease, led Gellhorn to look for something that would suppress it, and he found acetone.

Acetone is a transparent, colorless, mobile, and volatile liquid of a characteristic ethereal odor and a pungent, sweetish taste. On the skin it causes a sensation of cold. It is used in the laboratory for hardening tissues. In it the tissues shrink so rapidly owing to its hygroscopic qualities, that if left in the fluid for more than half an hour, they are too hard for the microtome knife. It was this hardening property of acetone which led Gellhorn to its use. He found the ulcerating surface of cancer could be hardened *in vivo*, the discharge being checked until the escharotic portion would be cast off. The resulting free surface could then again be hardened and occasionally it was possible to harden deeper portions or even the entire tumor, thus rendering the growth temporarily harmless.

The acetone treatment is indicated in any inoperable case of cancer of the uterine cervix, or of the surface of the body, in which the breaking-down area can be submitted to its action. The treatment should, if possible, be preceded by a thorough scraping out of the ulcerating area under anesthesia, otherwise the acetone is uselessly spent in hardening dead tissue. The curetted cavity or crater is then carefully dried with gauze sponges and one-half to one ounce of acetone is poured into it through a Ferguson or other tubular speculum. For this purpose the pelvis of the patient must be raised as in the Trendelenburg position. The narcosis is now interrupted and the patient left with elevated hips for fifteen to thirty minutes. Next the acetone is permitted to run out through the speculum by lowering the pelvis of the patient and the cavity is packed with gauze soaked in acetone. The healthy mucosa of the vagina and vulva are cleaned with sterile water and a dry tampon is inserted into the vagina to absorb any excess of acetone.

After the preliminary curretage and cauterization the regular treatment requires no further hospital care, is administered twice or three times a week beginning the fifth day after the operation, is

done without narcosis, and may be given with the patient in bed or on the examining chair in the office. The pelvis of the patient is raised and the tubular speculum inserted into the cancerous cavity. With progressive diminution of the crater, smaller specula are employed. The speculum is filled with acetone and held by the patient for half an hour and then emptied by lowering the pelvis. Care should be taken to prevent the acetone from running over the vulva or perineum. The normal vagina is not affected by acetone but on the vulvar mucosa and outer skin acetone produces a faint, whitish discoloration and an intense burning sensation which soon disappears and may be immediately relieved by the application of cold water. If vaseline is applied to the vulva, lower part of the vagina, and the speculum and after the acetone has run out the cavity is swabbed dry and a cotton tampon coated with vaseline, is introduced into the vagina before the speculum is withdrawn the intense burning sensation is prevented. The tampon is removed by the patient in a few hours.

The immediate effect of this simple procedure is to check any bleeding. The surface of the crater becomes covered with a white film. Wherever there has been an extravasation of blood, the discoloration is light brown. There is a marked reduction in the intense odor, the discharge at first becomes watery and soon disappears. With it disappears the former stench, and at the same time hemorrhages fail to recur, and after two or three weeks treatment a considerable diminution in the extent of the wound cavity is noticeable. This has been confirmed by several observers. The walls of the cavity become smooth and firm so that the finger cannot remove any friable tissue. Occasionally owing to this fact the preliminary curettage may have to be repeated.

Because of the checking of the weakening hemorrhage and discharge and the elimination of necrotic tissue and toxins, the general condition of the patient improves rapidly. Sensations of pain caused by the extension of the cancer to adjoining organs or nerve trunks beyond the reach of the acetone are not relieved; these require, as before, anodynes. However, they require less and can often be relieved by aspirin.

Gellhorn did not, and we have never been able to, find acetone in the urine of patients treated by us. Maier of Philadelphia, in one of his patients, was able to find a large quantity of acetone in her urine several hours after treatment.

The patients on whom acetone was used had passed beyond the reach of any radical operation and in some cases the cancer had consumed the greater part of the cervix and vagina. The treatment, in a simple and harmless way, has given these patients a period of comparative ease and comfort. Acetone is probably not applicable to cancer of the lower vagina and vulva, because of the pain it produces. We have had no experience with the salt of acetone, acetone bi-sulphite, which Gellhorn has just advised for use in these cases. It gives off pure acetone in contact with the wound secretions. He says its action is only slightly inferior to acetone. (1) Gellhorn, *Journal of Obstetrics*, May, 1909).

I am able to report also one case of cancerous ulceration of the surface of the body treated by acetone; a cyst of the back, which had broken down and become cancerous, in a woman 74 years old. This was completely healed by acetone. I want to thank Dr. Brooks H. Wells for his kindness in allowing me to report certain of his cases with mine.

The case reports following are selected as being typical of the conditions in which acetone is useful and of the results to be expected from its use.

Case I.—Mrs. B., aged 47, was admitted to the New York Polyclinic Hospital, service of Dr. Brooks H. Wells, on May 1, 1907. The patient was brought into the hospital on a stretcher in a very critical condition suffering from profuse hemorrhages from the vagina brought on by any slight motion, as coughing or turning in bed. There was a necrotic discharge which produced an odor unbearable to the other patients in the ward. Her temperature was 102°. She was very septic, pale, thin, and weak. On examination there was found advanced carcinoma of the cervix with a very large and deep necrotic cavity. Under ether anesthesia the cavity was scraped out and packed with gauze soaked in acetone. Gauze removed in twelve hours and replaced with fresh acetone soaked gauze. There was no bleeding, a slight brownish discharge, no odor. May 5. Some bleeding on wiping out the cavity which was stopped by acetone applied through tubular speculum. No odor. Temperature normal. Appetite good. Patient feels much better. June 7. Acetone applied through speculum every second day. No bleeding, odor, or discharge. Appetite fine. Has gained remarkably in strength and color. Discharged from hospital and went to her home in Vermont, where the acetone was continued by her physician. On October, 1907, he reported that Mrs. B. was in very good condition, attending to her home duties and not troubled by hemorrhage, discharge, or odor.

Case II.—Harlem Dispensary. Mrs. A., aged 42. Had been bleeding from the vagina off and on for six months with profuse stinking discharge, loss of appetite and weight; has complained of pain in lower abdomen for one month. Examination showed a large friable cauliflower-like cancerous outgrowth from the cervix uteri with involvement of anterior vaginal wall and left parametrium. July 1, 1907, a thorough excochleation was done. There was free bleeding, which was promptly stopped by the application of acetone. The cavity left after the scraping out was packed with gauze soaked in acetone. During the month acetone was applied through the tubular speculum every other day. No odor. No hemorrhages. No pain. Menses normal. Appetite good. General condition improving rapidly. August. She comes two or three times a week for treatment. Slight watery discharge. No odor. No bleeding. September. She attends to family and does washing. October. Appetite and general condition good, cavity 2 inches deep; walls hard. No bleeding. No odor. November. Cavity smaller; walls hard. No odor. Works regularly. February, 1908. Complains of pain, but is relieved by aspirin. Looks well. No discharge. May. Cavity about an inch deep. No odor. No blood. Requires morphin at times. June 30. Died of uremia from pressure on ureter. No odor or hemorrhages up to time of death.

Case III.—Mrs. B., aged 45. Patient had been treated by a physician for six months for hemorrhages and a stinking discharge, but no physical examination had been made. She was finally told that she must have a tumor and had best go into a hospital. August, 1907. On examination a tumor was found which extended above the level of the

umbilicus. In the upper part of the vagina was an irregular cavity the size of an apple involving all of the anterior lip of the cervix and extending up into the tumor. A diagnosis was made of fibroid uterus and carcinoma. The cancerous cavity was thoroughly cleaned out with a sharp curette and packed with gauze soaked in acetone. Treatment was continued by application of acetone through a tubular speculum at first every other day and later twice a week. October. No bleeding. No odor. Slight watery discharge. No pain or bleeding on coitus. Attends to home. Walls of cavity hard and firm. December. Husband took her West where she died.

Case IV.—Mrs. R., aged 28. Had borne seven children in eight years, the youngest being fifteen months old. No miscarriage. Menstruation began at fifteen and was normal. For one year she had been bleeding irregularly. For six months she had had a stinking vaginal discharge and because of this her husband had deserted her. Had some pain on micturition. Had lost weight and strength. June 9, 1908. Examination showed extensive carcinoma of cervix, anterior lip gone, and involvement of anterior vaginal wall and bladder. The sloughing, bleeding cavity was cleaned and acetone thoroughly applied. Bleeding was promptly stopped by the acetone. July 1. Patient returned for treatment; has had no bleeding until a week ago; odor has just returned. Examination at this time showed the cervix destroyed except for a small piece of the posterior lip, both anterior and posterior vaginal walls being involved. A large cavity extended to above internal os. She was taken to the Polyclinic Hospital and under ether the remains of the cervix were curetted away and the cancerous cavity scraped out, care being taken not to perforate the bladder or rectum. There was free bleeding which was stopped by acetone. Three days later acetone treatment was commenced at the Dispensary; cavity firm; slight brownish discharge; no odor. Two weeks later patient admitted that she was supporting herself by prostitution. No discharge; no odor. Patient remained under treatment irregularly, once or twice a week, all summer and during this time had no odor, discharge, or hemorrhage. Had to take ½ gr. morphine daily to relieve pain. In October was sent to Home for Incurables by her brother as she had no means of support.

Case V.—Mrs. C., aged 52. She had never been pregnant and her menstruation had never been more than an irregular show. In January, 1906, a surgeon amputated her cervix for a "growth." This operation was followed by a vesicovaginal fistula and she was sent into Dr. Wells' service at the Polyclinic. He operated but could not secure healing of the wound. A second operation was done by turning a cuff of the vaginal mucosa over the opening and thus closing the vagina. This failed to close completely a pin-hole opening being left. It was noted that the tissues were very friable, but there was no suspicion of cancer and a histological examination of the tissues was not made. In September, 1908, she came to me at the Harlem Dispensary with carcinoma involving the vaginal septum and the posterior vaginal wall. The finger could be passed through the septum into a cavity made up of bladder and vagina covered by firm, friable tissue from which came a stinking discharge mixed with the urine. Acetone was applied, the discharge lessened, and in a short time the odor disappeared. The patient was made comparatively comfortable. The acetone seemed to have no ill effects on the bladder. In October friends sent the woman to the Home for Incurables.

Case VI.—Mrs. G., aged 48. Came into the Harlem Hospital Dispensary in July, 1907. She had had three children and two miscarriages. Menstruation always irregular but without pain. She had been flowing on and off for seven months and had been told by her physician that it was the "change of life." For one month she had had a profuse, foul, and stinking discharge. Examination showed a carcinoma which had destroyed all of the cervix but a narrow rim, leaving a cavity the size of half an egg, extending into the uterus. Parametria thickened. Cavity curetted and packed with acetone-soaked gauze. Odor disappeared after the first treatment. Three weeks later the cavity was much smaller; walls firm; no bleeding; no odor; and only a slight watery discharge. Attends to her household duties. Has slight pain which is controlled by aspirin.

Case VII.—Patient of W. J. Furness. Mrs. F. 74 years of age, was operated on for a cyst of the back. The surgeon failed to remove all of the growth which later broke down leaving a large necrotic cavity over the region of the scapula. The odor from this was unbearable. Histological examination by Dr. Jeffries, Pathologist of the Polyclinic, showed carcinoma. I suggested acetone, which was applied and stopped the odor at once. After a few weeks of treatment the wound completely healed. Later the cancer recurred in the axillary glands which were removed at the Polyclinic. She is now in the Lebanon Hospital with a recurrence.

Case VIII.—Mrs. S., aged 40. No children. No miscarriage. Menstruation regular. Operated on two years ago for cancer of womb; uterus removed per vagina. Recurrence six months ago in the scar at the top of vagina. Treated by thyroid extract internally, *x*-ray over abdomen, and radium in the vagina. After the treatments she would have when she got home a profuse hemorrhage. This occurred after each treatment and was so severe at times that she had to be packed. I saw her; an examination revealed a carcinoma size of an apple at the top of the vagina. In the center of the growth was a hole through which the finger could be passed into a large cavity. The growth was curretted thoroughly, care being taken not to puncture the rectum. Bleeding was stopped by the application of acetone. With treatments every other day she was made so comfortable that she was able to enjoy life. No odor; no more hemorrhages; discharge very slight and watery. Four months later a fecal fistula formed from involvement of the rectum. Acetone treatment relieved her and kept down the odor, until her death a month later. For six weeks before her death she required morphine for pain.

2400 Seventh Avenue.

Death of Unexposed Interstitial Fibroma.—P. Begouin states that nodular fibromata, purely interstitial, may undergo an aseptic destruction by blocking of the single branch of the uterine artery that supplies each nodule. This caused a destructive degeneration of the growth that is not true gangrene, since no germs are present, but is of the nature of sphacellation. The author has had such growths removed and examined bacteriologically, and no microorganisms were found to be present. These growths are entirely shut off from contact with the air, and there is no method of access for bacteria. But if the artery supplying them is blocked by a thrombus they undergo death and degenerative changes.—*Journal de Médecine de Bordeaux.*

THE DIFFERENTIAL DIAGNOSIS BETWEEN CERTAIN FORMS OF TERTIAN MALARIA AND ENTEROGENIC INTOXICATION.

By HARRIS A. HOUGHTON, M.D.,

BAYSIDE, L. I., NEW YORK.

ASSOCIATE PHYSICIAN FLUSHING (L. I.) HOSPITAL AND NASSAU HOSPITAL, MINEOLA, (L. I.).

When we fail to relieve the little symptoms—the minor deviations from health which so often limit working capacity—criticism is apt to arise. Patients presenting themselves with malaise, headache, and other inconclusive symptoms are likely to be treated symptomatically and the precise diagnosis suspended. If one can reach the exact trouble, appreciation will reward the effort.

To realize the confusion which has arisen between the two conditions under discussion, one has only to live in a quasimalarious district and encounter many people fruitlessly taking quinine, either on their own initiative or at the suggestion of some physician. The next step is the nostrum. How many patent medicines are there advertised to cure both malaria and "biliousness!" The irony of this situation is best ilustrated by the fact that "Indian Cholagogue" is considered a most effective remedy for malaria in this district.

It will be well to define terms. Those who have had experience with tertian malaria will recognize the fact that hardly half of the patients in whose blood the *Plasmodium malariæ* can be demonstrated present the classical symptoms of chill, fever, and sweat on alternate days. Any one or all of these symptoms may be held in abeyance. It is in the less typical types, which are frequent, where mistakes in diagnosis are likely to arise.

The serious varieties of enterogenic intoxications, in which the bacterial floræ effect a complete change to anaërobic types, such as in certain anemias, are not at present under consideration, but the more or less transient varieties. I have come to regard this class as suffering from putrefaction in the bowel, not so much because they eat a surplus of nitrogenous food—for many of them do not—but because they eat more than their digestive powers can handle. The relation between the intake and digestive capacity is disturbed. This does not presume a complete alteration in the bacterial content of the bowel to anærobic types, but simply that the normal intestinal bacteria can intoxicate if they are presented with digested nitrogenous food which is unassimilated.

It will be noticed that the pathway marked out is a very narrow one, and more so perhaps than our knowledge warrants; but there are very good reasons for presenting it in this fashion. In the first place, the *Bacillus coli communis* does not attack native protein, if there is anything else on which it may act, but it does attack and disintegrate albumen conglomerates which we are in the habit of calling "peptones" and carbon nuclei. The anaërobes have the power of attacking native protein, but only with difficulty without the assistance of aerobes are they able to elaborate carbon nuclei fractions like indol. If, then, a patient presents himself with symptoms which can be positively traced to "indicanuria," we are either driven to the assumption that there has been a sudden complete reversal of the bacterial flora to anaërobic types, or that semi-digested and unassimilated food has been attacked by the usual inhabitants of the bowel. The quickness with which some of them get well under appropriate treatment argues in favor of the latter assumption. In the second place, the protein molecule fractions (peptones and carbon nuclei) are themselves capable of producing enteritis. This has been proven so many times, clinically and experimentally, that further discussion of this point is unnecessary. It is entirely conceivable that the integrity of the pancreatic secretion may be maintained and still a semi-catarrhal condition of the small intestine persist—sometimes for a long period—sufficient to prevent absorption. Probably it was this state of affairs which Sahli had in mind when he insisted that the presence of indican in the urine presupposes some degree of pancreatic activity. With these facts in mind, the differential diagnosis will not be difficult to carry in mind.

In no two conditions are the subjective symptoms so misleading as in chronic malaria and chronic "biliousness." If they are depended upon to give the proper lead, three-quarters will be wrongly diagnosticated. Both may be attended by headache of much the same type, nausea, and a feeling of *laissez-faire*. There is also a lack of ambition, inability to work or concentrate the thoughts. If the patient goes to the theater, he despises his own energy, no matter how good the play. At times there is a feeling of self-hate and irritability approaching hypochondria. At other times the deviation from health is so small as barely to be noticed. The only element which may help in the differentiation is that of periodicity. If this is marked, the diagnosis will lead toward malaria; but as a symptom it must not be depended upon.

A history of similar troubles in other members of the family, showing exposure to similar infection on the one hand, or similar habits of life on the other, will not help. If there is a distinct history of chill, fever, and sweat in previous years, there is probability that the infection with malaria may have existed in latent form. To be of value, the history of such an occurrence should not show an infection older than three or four years unless there have been periodic outbreaks of a similar nature. The tendency to eat hurriedly, a relative excess of meat or acid foods, or the habit of excessive activity after eating, will tend toward a diagnosis of enterogenic intoxication. It has not been my experience that chronic malaria shows itself in acute exacerbations to any extent in the winter or spring months. Suspicious cases usually turn out to be "spring fever."

The bilious sclerotic, or yellow, sallow skin, may accompany either condition. The familiar blue appearance of those suffering from subacute malaria rarely is found in enterogenic intoxications. In both the tongue may or may not be coated, or there may or may not be eructations of gas and acid. The acidity of the gastric juice cannot be held as a criterion, as there may be indicanuria with an acidity or hyperacidity. If the liver is enlarged, the diagnosis leans toward enterogenic intoxication; but more often it is not enlarged. Enlargement of the spleen points towards malaria, but even in some of the most chronic forms it has not been my experience to find palpable spleens. In enterogenic intoxications it is often possible to feel solid masses of feces at various places along the large intestine, or hardened scyballous enteroliths if the abdomen be thin and flaccid. In about a third of the cases, particularly of the more acute forms, a spot of

maximum tenderness will be found over the head of the pancreas. The appendix is often tender, and there may be chronic appendicitis. If the appendix is not involved, the sympathetic ganglia internal to the appendix will not be tender.

Without discussing the microscopic or fermentative properties of the stools in enterogenic intoxications, it is possible to gain many diagnostic points from their macroscopic examination. The following features will often, but not always, be noted: There may be well-defined strata of material differing from each other in consistency, color and the presence of mucus and other anomalies, the first part of the stool having a tendency toward hardness and the latter part to formless softening. This is particularly true of those cases which resemble the first week of typhoid in their behavior. A more or less homogeneous stool, accompanied by mucus, of light color, and giving out a foul odor, is also characteristic. A perfectly normal person should pass stools with practically no odor and its presence in excess indicates putrefaction.

To place any reliance on the symptom of constipation without further investigation will lead to error in judgment. The constipation of rectal hypertonus rarely of itself leads to enterogenic intoxication. It is more common to hear these patients say that they have two or even three stools a day than it is to hear them say that they are constipated. Each may be present without the other.

In the types of malaria under consideration there is little change in the urine except when the fever is high. In that event the urine is similar to that passed during the course of any simple fever, with high concentration, precipitates of urates and sometimes (though rarely) a trace of albumin. In enterogenic intoxications there are characteristic changes. It is apt to be of high specific gravity (except when complicated by contracted kidney), high colored, and hyperacid. When the intoxication manifests itself in an acute manner or has extended over some time, a trace of albumin almost invariably can be detected with the picric acid test or even a marked trace with Heller's test. Further evidence of the kidney irritation is to be found in the accompanying hyaline and granular casts, which are usually quite numerous. If the kidneys have previously passed urine free from albumin, these symptoms will decrease as the patient recovers. The presence of indican and other products of bowel putrefaction in the urine needs special consideration. In this kind of protein poisoning (*i.e.* the kind not occurring as the result of specific infection of the intestinal contents) the indican test with Obermeyer's reagent is very dependable. My experience coincides with Anders, who recently said (*Archives of Diagnosis*, April, 1909), that there is an increase in the indican reaction in practically all cases. (Houghton, *American Journal of the Medical Sciences*, April, 1908.) It will correspond to 100 or over on Otto Folin's scale. Oftimes the reaction with Ehrlich's aldehyde (dimethylamidobenzaldehyde-para) indicating phenol does not show an increase. In the absence of both of these reactions, one may feel that the bowel is in a hygienic condition. On the contrary, the presence of an excess of indican is presumptive evidence of protein poisoning, whether the malarial organism is found in the blood or not.

Simple hemoglobin decrease may be found in both conditions, but is more frequent in malaria of the chronic type. The presence of the *Plasmodium malariæ* detected in the red cells by the microscope is conclusive, whether the indican of the urine is high or not, and calls for the administration of quinine. It is reasonably certain, on the other hand, that if the organism is not detected after two or three careful searches, that the patient is not suffering from malaria, but is, if the indol excretion is large, a victim of enterogenic intoxication. It has been demonstrated that the peripheral blood may not show the plasmodium, while blood from the spleen does. Such cases must be rare, however; for in my series, when such a condition has been suspected, the disease has turned out to be something else. The plasmodium of malaria does not affect the leucocyte count nor alter the differential count to any appreciable degree. In severe infections, there may be a slight mononucleosis, with some hemoglobin destruction. In enterogenic intoxications the picture is always different, betraying its septic nature. In severe grades with fever, and probable involvement of the mucosa, the leucocyte count may show as high as 20,000. To differentiate in such a situation between enterogenic intoxication and appendicitis or gall-bladder disease sometimes requires a high grade of diagnostic ability, many cases of so-called catarrhal appendicitis being no more or less than severe intoxication from putrefying intestinal contents. In the milder forms the leucocyte count rarely reaches 12,000, and in the mildest forms it may be normal. The differential count will oftentimes show a relative increase in polynuclears. If there is an eosinophile increase, hookworm or some other macroendoparasite should be suspected immediately.

The presence of malaria in the blood does not seem to alter the arterial systolic pressure, unless the condition has existed long enough to cause a slight simple anemia and secondary hypotension. With enterogenic intoxications, however, the conditions differ somewhat and require some explanation. It is possible to differentiate two kinds of people who habitually suffer from this trouble. The first is found almost exclusively in women, probably resulting from lack of general tone, deficient digestion and exercise. Among them neurasthenic symptoms predominate. The second, found in both men and women, belong to the plethoric and overfed who live sedentary lives. In the former class decrease of the indican reaction will be accompanied by a rise in systolic arterial pressure from possibly 95 mm to normal, and ergot will help in the cure. In the latter, there is apt to be hypertension, particularly if there are evidences of kidney insufficiency or irritation, or the process has extended over some time. The pressure will often register as high as 140 mm. Should it go above that point, one may feel sure that there is a complicating contracted kidney, or abdominal arteriosclerosis. The pressure, of course, may remain normal, either with or without kidney involvement.

Fever may be present or absent in both conditions. In malaria (of sub-acute or chronic types) the temperature changes are gradual, rarely go over 102° and the changes show a tendency to diurnal periodicity. The relation of the temperature to the pulse rate follows the "normal" course, as shown by other infectious diseases. The reverse of this is usually true in enterogenic intoxications. The temperature is higher than the pulse rate would seemingly call for. The tendency to sudden changes in temperature, particularly in children, is very great. One hour will show it as high as 103° and the next

as low as 99.5°. It may rise or fall several times during the day or show a marked remission after the passage of a large stool. The "febriculæ" of children and of the puerperium in a large majority of cases is due to the fact that the bowels have not been sufficiently cleansed.

In a goodly percentage of cases the two conditions occur simultaneously, as shown by the examination of the blood and the urine, probably bearing no other relation than that the fever of the malaria may diminish the secretion of the digestive juices. Where the two are combined, many cases of malaria will not yield to quinine until the liver and intestinal conditions are treated.

Positively do dependence can be placed on the fact that massive doses of quinine temporarily relieve the symptoms of enterogenic intoxication. There is ample evidence to show that quinine will produce a favorable temporary effect, either by stimulating the secretion of digestive ferments, restricting the activity of intestinal bacteria, or increasing oxidation (detoxicizing) capacity. The symptoms under these conditions will rarely be permanently relieved and recurrence will follow in a few days. For this reason there are many people who have become habitual users of quinine, thinking they have malaria. Osler has said, "The physician who at this day cannot treat malarial fevers successfully with quinine should abandon the practice of medicine." True malaria of the tertian type always yields to quinine, and if the symptoms persist after its intelligent use, that of itself is sufficient evidence that a mistake in diagnosis has been made.

Finally, it must be noted that few cases of indicanuria can be cured so long as the patient remains on the diet or pursues the habits of life which caused it, or by the simple exhibition of calomel and soda. As long as the excess of indican persists in the urine, the intestines are in an unhealthy and unhygienic condition and need attention.

SPASTIC CONSTIPATION, A SYMPTOM.*

By JOS. N. LeCONTE, M.D.,

ATLANTA, GA.

LECTURER, DISEASES OF THE STOMACH, ATLANTA SCHOOL OF MEDICINE, GASTROLOGIST TO THE PRESBYTERIAN HOSPITAL.

In past decades, chronic constipation was classed as a separate disease and treated as such, very little attention being paid to its varieties, or to its causation, direct or remote; but more careful clinical study has established the causative relation of many diseases to chronic constipation, and the number of cases which are being diagnosed as genuine idiopathic constipation is becoming smaller and smaller.

Two general types of chronic constipation are now recognized, viz., atonic and spastic, which differ in their symptoms, and are amenable to an entirely different plan of treatment; but even now current medical literature affords very little information concerning spastic constipation and its treatment. As the name implies, spastic constipation depends upon a spastic contraction of the longitudinal and circular muscular fibers of the intestinal wall, caused by irritation or inflammation. An analogous condition to this is seen in the obstinate constipation and colicky pains of chronic lead poisoning; in which condition, the splanchnic inhibitory nerves of the intestinal ganglia are believed to be paralyzed, and permit of a hypertonicity of the intestinal muscular fibers. Spastic constipation is much more apt to be encountered in nervous, high-strung individuals, and occasionally cases have been reported which seemed to have no other cause except a neurosis.

It also appears that irritation in the uterus, bladder, or prostate, may excite, reflexly, acute attacks of spastic constipation, when no anatomic changes are demonstrable in the intestine. Anal fissure or ulceration of the rectum or colon may also present this symptom. Spastic constipation very often develops upon the basis of an atonic constipation, which may have existed for years, and in this case generally marks the oncome of catarrh of the colon. It is this phase of spastic constipation that I have met with most frequently and to which these remarks are chiefly directed. I can heartily agree with Dr. Crummer of Omaha in his epigrammatic statement that "In the medical wards of the Vienna General Hospital the most frequent diagnosis written on the slate at the bedside is 'M.C., morbus communis,' an euphonious name for tuberculosis, but in America, even as widespread as is tuberculosis, if morbus communis were used to refer to the most frequent disease, it would have to be another M.C., referring this time to mucus colitis."

On going over my case records covering the period of the last three years, I find there were 191 having catarrh of the colon alone or in conjunction with other disorders, and of these 191 there were 76 cases, or 40 per cent., who had spastic constipation, more or less pronounced, as a symptom. Any of the causes, then, of an atonic constipation, or a chronic colitis, may be the indirect cause of a spastic type, chronic colitis affording an excellent opportunity for the development of this enterospasm. The patient complains of periodical attacks of sharp cutting pain in the course of the colon, or radiating from the umbilicus, especially before the expulsion of gas or feces, and in the intervals more or less dull aching pain in the lower abdomen. These attacks may come on at intervals of several hours or days, or may be continuous for weeks at a time.

Laxatives if effective at all are only so in large doses, and then accompanied by considerable pain. I have seen a patient with this condition who had exhausted the list of milder purgatives and had come to the use of four compound cathartic pills every alternate night which only resulted in one very small movement and almost unbearable pain; in this case full doses of belladonna promptly effected a copious evacuation. If enemas are used, the water at once returns perfectly clear, or if it succeeds in passing the contracted segment, fails to return at all. The stools are generally insufficient in quantity, either hard or putty-like in consistency, pencil sized or ribbon shaped or scybalous, and accompanied by a larger or smaller quantity of mucus. The mucus varies in quantity from day to day, and may coat the surface of the stool as a sort of membrane, may appear like macaroni, the movement may be entirely made of mucus, or the amount of mucus in the feces may be so scanty as to require grinding in a mortar with water and placing in a black plate for its detection.

Patients often remark with amazement the small caliber and small quantity of the feces voided after so much effort and pain, like "the mountain delivered of a mouse." They also generally complain of a sense of incompleteness after defecation, and

*Read before Fulton County Medical Society, June 17, 1909.

of fullness in the rectum, though examination shows the rectum to be empty, whereas in the atonic form a sense of relief and well-being follows defecation. In accordance with the old idea that all constipation is atonic constipation, and requires stimulation by coarse food, patients often report that they have been faithfully taking dried figs, raw wheat bread, wheat bran, raw vegetables, and even sand, all of which promptly aggravated their condition.

On physical examination the ascending or descending colon and sigmoid, and sometimes the entire colon, may be palpated and rolled back and forth under the examining fingers as a hard rope-like structure, quite tender to pressure. On digital examination the rectum is generally empty of feces, and is felt to contract firmly on the examining finger. In typical cases of atonic and spastic constipation the differentiation between the two is easy, but inasmuch as one is often developed upon the other we may meet with transition stages which are confusing.

In atonic constipation there is no pain or excessive flatulence, no corded or tender condition of the colon on palpation, but it may often be felt filled with fecal matter; laxatives and enemata are effective in producing a stool. The stool is generally hard and of large caliber, sometimes goose-egg shape in rectal constipation, and no mucus is visible, except perhaps a shellac varnish appearance on the surface.

The subjective and objective symptoms of spastic constipation may simulate those of chronic appendicitis or gall-bladder disease if the enterospasm, pain, and tenderness is centralized in the cecum or the right segment of the transverse colon; indeed, these conditions coexist, not infrequently, in the same patient.

Spastic constipation may be continuous for months, or may come on at irregular intervals, the movements between times being atonic in type, and of large caliber, or more frequently they may take on a diarrheal character, especially after taking cold, or after gross errors in diet, but always accompanied by mucus.

Spastic constipation occupies the center of the stage in that peculiar malady of neurasthenics, mucous colic, the pathology of which is still a subject of dispute among authorities. Nothnagel and many others have held it to be a neurosis of secretion similar to attacks of bronchial asthma; while Paul Cohnheim and his school claim that all cases have anatomical changes in the intestinal wall as a basis, and the mucous colic and membranous enteritis are only different manifestations of a chronic catarrh of the colon, as influenced by a condition of neurasthenia. From 70 to 90 per cent. of the cases of mucous colic occur in neurasthenic, hypochondriacal, hysterical women, many of whom have a condition of enteroptosis, or some disturbance of the uterus or ovaries. This disease is characterized by sudden severe attacks of colicky pain and obstinate constipation, which may be accompanied by nausea, collapse, and subnormal temperature, which, in turn, is followed by the passage of large quantities of membranous mucus. The patient then experiences relief for a variable period of time, but may have other attacks after several days, weeks, or months. The mucus is opaque, leathery, and often is fashioned in a membranous tubular cast of the bowel, one foot or more in length. Microscopic examination of these casts shows no fibrin present, and its membranous character can only be explained by its long sojourn in the bowel, and the dessicating process which it undergoes. Repeated attacks weaken the patient, render her morbid and hysterical, and altogether it presents a condition most obstinate to treatment.

Successful treatment will, naturally, depend upon the discovery and removal of the causes, remote or immediate, in that particular case. The history of the patient should be carefully elicited, and a physical examination made which should include examination of the gastric contents, urine, and feces. All measures to regulate and strengthen the nervous system are, in general, to be employed to the fullest extent. Supervision of the personal hygiene in each case is therefore imperative, abundance of out-door life, rest after meals, regular and sufficient hours of sleep, the drinking of a proper amount of water, avoidance of violent exercise, or excessive mental strain. The general plan of treatment here outlined is also indicated in chronic catarrh of the colon, which is generally the cause of the spastic constipation.

Neither the coarse refuse diet of atonic constipation, nor the concentrated bland diet advocated by some for spastic constipation, are suitable, but a middle ground between these two. Food should not be too concentrated, and too completely digested, thereby promoting constipation, nor should it contain hulls and husks of vegetable fiber, fruit skins, berry seeds, gristle of meat, etc., nor should those foods be used which irritate chemically. Every mouthful of food which is swallowed by such a patient must be so selected, so prepared, and so masticated that it would pass without difficulty through a fine seive.

In a general way, if there be no special contraindication, we can use bouillon or purées without grease or tomatoes, young tender vegetables thoroughly cooked without grease, cream, sweet milk, buttermilk, fermented milk, tender boiled or roast beef, mutton, or chicken, boiled or broiled fish, well cooked crusty bread made from finely ground flour or meal, raw, soft-boiled, or soft-poached eggs, gelatin, butter, olive oil, stewed apples, peaches, prunes, baked apples, without sugar and all having been put through a seive and freed from all lumps, skins, and seeds. To be forbidden, are: coarse bread, oatmeal, all fried foods, pork, all potted, canned, cured, or smoked meats or fish, tomatoes raw or cooked, radishes, cucumbers, raw onions, cabbage, all raw fruits, figs, berries, nuts, all salads, pickles, condiments, sweets, pastries, cheese, alcoholics. Hot sitz baths, hot stupes on the abdomen, and hot carminative teas are often of value in the acute crises of pain.

General massage of the body and extremities is permissible, but massage of the abdomen is strongly contraindicated, as is also vibration and electric currents, excepting galvanism.

The galvanic current can be used to advantage especially in those cases which have no catarrhal colitis, but are developed upon the basis of a neurotic spasm. One should employ one of the types of rectal electrodes which is so protected that the metal tip does not come in contact with the mucous membrane, and the rectum and sigmoid being distended with saline solution from a fountain syringe; from two to ten miliamperes may be used for a period of five to ten minutes.

The most valuable single aid to treatment in this condition is the high colon injections of olive or

cotton seed oil; this method, described by Fleiner of Heidelburg, some fifteen years ago, has not been employed as generally by the profession as it deserves. The oil should be introduced as high as possible, through a colon tube, in quantities of six to twelve ounces, at bed-time, and should remain in the bowel all night; the patient should use this in the knee-chest position, or on the back, with the hips elevated. This treatment acts as a curative agent for the colitis, aside from the relief of the constipation. Belladonna and hyoscyamus, by mouth or rectum, and atropine hypodermatically, afford considerable relief to the patient by their effect on unstriated muscular fiber, and may be continued in the intervals between the acute attacks. The routine use of drug laxatives, without any attempt to discover or remove the cause, is criminal in any chronic constipation, and especially so in the spastic type.

In those cases where spastic constipation is a manifestation of catarrh of the colon, I have found that, however faithfully treatment is maintained, a condition of cumulative autointoxication and intestinal putrefaction arises in the bowel periodically every four to eight weeks, which can only be relieved by calomel purgation; fortunately, these attacks recur at longer and longer intervals, till finally they disappear. It may be necessary to employ gentle laxatives in combination with the other measures, in the beginning of the treatment. In those cases where dry scybalous stools persist in spite of suitable diet, etc., agar-agar with or without watery extract of cascara, may be used to advantage to cause a copious mushy stool. This was first suggested by Adolf Schmidt of Halle, and operates on the principle that when ingested with mushy food the dried agar-agar absorbs water, swells up and becomes slimy, passes through undigested, adds volume to the feces, and has no irritant effect, mechanically or chemically.

If enteroptosis is present, a properly fitting bandage should be applied. Divulsion or division of the sphincter ani is valuable as a remedial agent if a fissure or similar condition is located at the anus, but otherwise it is useless.

Pronounced cases of mucous colic, and membranous enteritis, as seen in neurasthenic or hysterical individuals, often require three or four weeks rest-cure, in connection with the other measures described above. In very obstinate cases of this kind, cecostomy, or appendicostomy has been performed, and colonic lavage performed through the fistulous opening, a closure of the fistula being accomplished by operation after recovery.

A CASE OF MONGOLIAN IDIOCY.

By ALFRED. M. HELLMAN, B.A., M.D.,

NEW YORK,

ANESTHETIST TO THE GERMAN AND HAR MORIAH HOSPITALS.

On reading a report in the Medical Record of June 5, 1909, on the presentation of 14 cases of Mongolian idiocy by five members of the Clinical Section of the Royal Medical Society, I was struck by the absence therefrom of several interesting points, especially the irregularity of date of bone development in such cases. I make this absence my excuse for reporting an isolated case which I showed on May 4, 1909, before the German Hospital and Dispensary Clinical Society.

Family History.—In the parents of the young patient, whose photograph accompanies this article (Fig. 1), there is no history of cancer, tuberculosis, syphilis, or insanity. There is no consanguinity. Both have enjoyed much more than the average good health.

Personal History.—The patient himself is the youngest of three, the other two being normal individuals. His mode of life is that of most children of the slums. He recently had pneumonia, and is supposed to have had rickets in infancy. If he had rickets there are certainly at present no signs remaining. Though rickets is common in these cases of Mongolian idiocy or imbecility, or, as it is frequently called, Kalmuc amentia, I prefer to believe that in this case the so-called rickets was but the symptom complex of the early unrecognized Mongolian type. The mother noticed that when the child was two days old he could not suckle as had the other children. The father states definitely that the now existing cranial deformity and likewise the rickets existed at birth. The child first learned to creep when four, and to walk when four and a half. He never exhibited the slightest emotion until over four years old, when he became frightened at the sight of a street car. His teeth first appeared after the third year. The present teeth, except two upper and one lower incisor, still belong to the first set. They are all in a horrible state of decay, which started in shortly after the teeth appeared. Though nine years old, he is still unable to dress himself. He has not advanced beyond the kindergarten class of the public school. He plays around like a child of four. His mother considers him a good child. He always smiles and is good natured and sweet tempered. Tears are almost unknown. His hearing is good, but his sight is not of the best, or at any rate the powers of observation are very poor.

Fig. 1.

Physical Examination.—Mere superficial inspection shows he is imbecilic. He wears a perpetual grin, causing an abnormal wrinkling of skin for his

age. He is physically underdeveloped for his nine years. The circumference of his anteroposteriorly flattened skull is 18½ inches, the average normal being 21. His chest is 23¼ inches to a normal of 25 4-5. His height is 43 inches, whereas the normal is 52 1-5 inches. He possesses an ample amount of adipose tissue and seems well nourished. The skin, especially of his hands, is very dry. His head, as before stated, is flattened from before backward. The fontanelles are closed. The forehead bulges. The face is full-moon shaped. The mouth is large and has slightly upturned corners. It is usually open. The tongue, as emphasized by Dr. Thomson (*British Medical Journal*, 1907), though it protrudes less constantly than in cretinism, here is thickened, irregularly fissured, and the papillæ are swollen. The palate is high and narrow, the cheeks are flushed. The nose is squatty or button-shaped, the bridge flat and sunken, the nostrils triangular and point more forward than down. The ears are small and round. The eyes show that characteristic which caused Dr. Down, who first described this form of amentia, to speak of it as the Mongolian type—namely the palpebral fissures slanting down and in with redundant skin to the upper lid and marked epicanthus. There is slight exophthalmos and a

Fig. 2.

marked strabismus. The irides are slightly speckled. The eye backgrounds are normal. Chronic inflammation of the upper respiratory tract is seen in persistent blepharitis, chronic rhinitis, and frequent cracked lips. All these are notably common in this condition.

The neck and thorax are normal. There is no heart lesion. The lower half of the abdomen is slightly protuberant. The pelvis is small, pushing the bladder upward, making it rather prominent in the abdomen. There is a small ventral hernia just above and to the right of the umbilicus.

Now, examining the extremities, we come to the square fat hands with the short fifth finger and relatively shorter thumb, which makes these Mongolian imbeciles so clumsy with their hands. It is well known that the various carpal bones develop their ossification centers at different ages, so that from an *x*-ray picture of the hand we can tell the approximate age of a young patient. At the suggestion of Dr. Stetten I went carefully into this matter in the hope of learning to what age my patient's development had been brought. At nine years the ossification centers of all carpal bones except the pisiform should be present and give full-size shadows with the *x*-ray. Here we find (Fig. 2) that none have reached full growth. The semilunar which usually appears in the fifth year is absent and the pisiform which shows up ordinarily not until the twelfth year is already present.

To add to all these troubles our young patient has a slight persistent albuminuria, anemia, and a few annoying hemorrhoids.

Tuberculosis, syphilis, alcoholism, and severe uterine prostration from exhaustion during gestation—these things in the parents are given as frequent etiological causes. None of these played any rôle in my case, and the real cause is probably as yet unknown. It is equally common in male and female and in the first born as in the last of a large number. Race, climate, and social position need not be considered.

The diagnosis must generally be made, as in this case, by exclusion; by the flat skull, the bulging forehead, the Mongolian eyes, the thick, heavy tongue, and the chronic inflammation of the upper respiratory tract. This type of idiocy is more easily recognized in children between the first and fifth years.

Mongolianism must be differentiated from other forms of feeble-mindedness or imbecility as seen in children. Including Mongolianism, Holt mentions eight forms of idiocy.

1. Cases lacking a brain or lacking the frontal lobes evidently do not include our patient. Children of this class never live more than a few months.

2. Hydrocephalus.—Our patient has an undersized, not a large, head.

3. Microcephalus would give a smaller head than our patient has. The head would be flattened from side to side instead of from before backwards, and development would be even less far advanced.

4. Paralytic forms are all ruled out by the entire absence of paralysis.

5. Cases of inflammatory origin follow meningitis, which our patient has never had. His trouble dates from birth.

6. Epilepsy is ruled out by the absence of convulsions.

7. Amaurotic family idiocy would give blindness and the typical ophthalmoscopic picture. Our patient has very fair vision.

8. From cretinism it is distinguished by the eyes; by the high forehead (all cretins have low foreheads), by the thick fissured tongue; by the chronic inflammation of the upper respiratory tracts, and by the ineffectuality of thyroid treatment.

The pathological picture, though not very clear, has as its chief feature a lack of development of the cells of the brain in all its parts.

The prognosis is bad. These children will not improve as will cretins. Frequently they are affectionate, sweet-tempered, and well-behaved. They have a cheery smile which leads their parents and teachers to work hard with them. They learn but poorly and are a great disappointment in the end. Even to teach them to use their hands is of no avail. The hands being fat and square and the thumbs short, they always remain clumsy. Very few of these patients reach maturity. They die of some intercurrent infection to which they are so very susceptible.

The treatment is unsatisfactory. No drugs are even advised. So little can be done along educational lines that they are best off in institutions with others of their kind.

2 West Eighty-sixth Street.

NONSPECIFIC USES OF ANTIDIPHTHERITIC SERUM.

By F. M. FERNANDEZ, M.D.,

HAVANA, CUBA.

CHIEF OF THE OPHTHALMOLOGICAL CLINIC OF DR. J. SANTOS FERNANDEZ, OPHTHALMIC AND AURAL SURGEON TO THE MAZZORA HOSPITAL, OPHTHALMIC AND AURAL SURGEON TO THE "SANTA TERESA DE JESUS SANATORIUM."

NUMEROUS investigators have made important studies in the use of antidiphtheritic serum in conditions other than diphtheria, and the results in the majority of the cases allow us to suppose that we have in this serum a valuable therapeutic agent in the treatment of various infections, either general or local. Its use is every day more extensive, and on account of its innocuousness, as even in massive doses there is little danger, we have no doubt that very soon it will be extensively used in the treatment of numerous infections.

How does antidiphtheritic serum work after it is injected in the human body? By not only increasing in a positive way the vital power of the individual, increasing his opsonic index, but also by reenforcing the resistant powers of the organism whatever they may be, and allowing them to attack and destroy more vigorously than before the toxins that invade the human body and are the products of the various infections.

It is not only in the cases of general infections that the serum gives good results, but in many localized infections also. Taking, for example, the eyes, in which most of our experiments have been conducted, we have learned that suppurative keratitis, of whatever origin, is always influenced in a favorable way by this serum. Dr. J. Santos Fernández[1] of this city having become convinced of the inefficiency of the usual treatment of this disease, was inclined to try the one recommended by Toulieres,[2] which consists in the injections of antidiphtheritic serum, and he reports a few cases from his clinic that were favorably influenced by the serum. Since his work was published we have treated at his clinic several more cases of suppurative keratitis, with the subcutaneous injections of antidiphtheritic serum, and have had very good and prompt recovery in all the cases thus treated, attention being called to the rapidity with which the absorption of the purulent exudate in the anterior chamber began.

In other eye affections it has also been used. In fact, Darier[3] affirms that in the infectious ulcers of the cornea, in the infections by penetrating wounds of the eyes, in the serious complications that sometimes arise after cataract operation, in cases of infectious iritis, in herpes zoster ophthalmicus, etc., the affection is rapidly checked by two or three injections. In these cases there is noted first the absence of pain, and, afterward, rapid recovery, with, as a rule, remaining vision, which is better the earlier the serum is administered. Alonso,[4] in a recent work of recapitulation of the different sera, affirms that they facilitate the rapid recovery of the ocular diseases mentioned; and he prefers the antidiphtheritic serum on account of its almost complete innocuousness. In several of the general diseases this serum has been used with success and has given its best results in respiratory affections. In asthma it has been proved that several cases have been cured by its use; and in our national literature, and only a part of it, we have seen that Dr. Ruiz Casabé described,[5] in 1898, a case of asthma cured by injection of antidiphtheric serum. Dr. R. Grau[6] has very recently described three cases of the same disease, also cured with the serum. In pneumonia it has also been used, and sometimes its use has been followed by success. Grau[7] also reports a case of bronchopneumonia and another of influenzal pleuropneumonia, treated with the serum with satisfactory recovery in both cases. Muñoz[8] describes a case of a boy suffering from bronchopneumonia with serious symptoms. He injected the antidiphtheritic serum which produced a very marked and prompt improvement, and the patient was rapidly cured.

In a recent epidemic of measles in Wajay (Havana Province) and its surroundings, there were a great number of complicating bronchopneumonia cases and a colleague that treated a good number of these cases, tells me he has used the serum in several, with prompt and notable success.

It is evident that this serum has an almost specific action on some microbic elements that are not those of diphtheria. Besides, as it is not dangerous, we think that its use ought to be more generalized, at least, as an experiment to study it in a systematic way, and to derive from its use as much benefit as possible.

Very recently there was published[9] a paper referring to the unpleasant results of this serum. The author, Dr. H. F. Gillette, says, that in his opinion if we would eliminate the dangers of administering serum to the asthmatic, we would cure over 50 per cent. of all cases of asthma by antitoxin; but he thinks, until that is done, it will never be a popular procedure.

In a review of the literature Dr. Gillette reports twenty-eight cases in all in which collapse or death has followed the administration of horse serum. Of these, fifteen died. The doses employed were not very large; but most of the patients had previous respiratory troubles of some kind, and, as he says, "in the report of the cases it will be noted that some had an irritation of the mucous membrane of the eyes, nose, and throat; and some had asthma when about a horse or stable."

We would say that the small number of cases described is not a drawback to the popularization of the procedure, and furthermore we can begin giving small doses of the serum, proving, as it were, as we do with any other drug. Take opium for example: we know that it is a dangerous drug, more so in children; and yet we employ it, taking such precautions as may seem best, a procedure which may also be applied to the antidiphtheric serum.

In conclusion, we will say we believe that the trial stage of this serum has ended, and that it has entered with honors into general use, adding a very potent and valuable agent to our therapeutic armamentarium.

INDIGESTION.

IN a recent number of the *Practitioner* are some common sense articles by practical members of the medical profession on ordinary every day ailments. After all, it is the small complaints that count the most, for they trouble the greatest number of people, and if not guarded against lead to serious results. Some common ailments, of course, are but manifestations of grave maladies, but whatever their origin may be, it is at all times well that they should be diagnosed and treated as quickly as possible. Perhaps the most common, as it certainly is the most unpleasant of all the so-called small ailments, is indigestion, and this affection is discussed in the *Practitioner* by F. J. Smith of London. After dismissing from present consideration those cases of indigestion which are the symptoms of gross organic disease and which do not seriously enter into the daily routine of general practice, Smith divides those suffering from dyspepsia into three classes, babies, children, and adults, and records his opinion that it is in babies that the most genuine cases of indigestion occur, *i.e.* cases of a simple lack of sympathy between the stomach and its contents. As to the artificial feeding of infants, the cause undoubtedly of most of the indigestion that occurs among them, Smith holds decided and somewhat original views. He is quite sure that much harm, far more than is dreamt of by the scientific sanitarian, is done to babies by the boiling, or so-called sterilization, of milk, which renders milk less suitable for the nutrition of the infant. Naturally, he insists that, so far as possible, the milk-yielding cows should be healthy and that the sanitary arrangements and cleanliness of the milking sheds and dairies should be as nearly perfect as can be. He also enters a protest against the view that babies cannot digest a small proportion of carbohydrate material.

The indigestion of children is referred to briefly, and much that occurs up to the age of fifteen or sixteen years is laid at the door of the manner in which children, and especially American children, are brought up and the absurd way in which they are fed.

As for the indigestion of adults, Smith is quite satirical with regard to the varieties and subvarieties of description with which the scientist of to-day has exercised his ingenuity, and declares it to be his opinion that with each invention of an instrument for exact investigation we lose a proportion of that clinical instinct and delicacy of finger touch which were so highly prized by our predecessors and which enabled them to be astonishingly accurate in diagnosis. "We lose, too," he says, "that personal interest and keen observation of the patient which are so invaluable; our minds become concentrated on the disease, and we forget the patient with all his own natural resistance to, and most extraordinary and unknown powers of overcoming disease, if encouraged to use these powers and if not overwhelmed with drugs and courses of treatment." The author is further of the opinion that the multiplicity of names given to indigestion are useless and ofttimes misleading.

The various symptoms of indigestion are briefly run over and the causes thereof suggested. It is pointed out that in flatulence after meals, the later its occurrence after food the less likely is the case to be one of simple indigestion. A mere sense of fullness after a meal is almost certainly due to functional trouble; if it occurs later and is then associated with some pain, it points strongly in the direction of gastric or duodenal ulcer. With respect to the causes of simple indigestion the most frequent is the hurry and bustle of modern city life, the rush for the train with a hurried breakfast half masticated, an equally hurried lunch, or with some, especially elderly people, a heavy lunch with a liberal allowance of alcohol, the rush back home after a heavy day's work and a good square meal with more alcohol. Smoking, too, on an empty stomach is strongly deprecated if one wishes to avoid indigestion. Attention is drawn to the fact that worry is one of the main causes of indigestion and that this cause is more potent with women than with men.

So far as diet for indigestion is concerned, Smith says there are only a few fads he goes in for personally; one of these is to assure all his patients that cold boiled ham or bacon is of all flesh foods the most easily digested. The other fads are that chicken is less digestible than beef and mutton when the latter are properly masticated; that there is no difference between red and white meat in digestibility; that fish need not necessarily be boiled, and lastly that if any patient likes to try any fad of the faddists, it will probably do him no harm to do so.

The author is altogether in accord with the medical policy of the present day in giving few drugs. His armamentarium for indigestion contains iron, bismuth, saline purgatives, alkalies and acids, and a few aromatics. In deciding what drugs to give, one should divide patients into the full blooded and the anemic, because it is of no use in the indigestion of anemic girls to give drugs for indigestion until the anemia has been helped or cured by iron. In administering drugs for indigestion the following routine has been evolved: To let the patient have the last meal of the day at 5 P. M., and then to give medicine, which generally consists of 2 drams of subnitrate or carbonate of bismuth and 1 dram of bicarbonate of sodium at 10 at night, at 2 A. M., and at 6 A. M. There are, however, obstinate cases of indigestion which will not yield to ordinary treat-

ment, and for such as these the remedy is a short confinement in bed. The great advantage of bed with limited bread-and-milk diet and the evening administration of bismuth and soda, is that, according to Smith, it will almost without any exception cure those cases which lie on the borderland between simple and organic dyspepsia.

There is much sound truth in this dissertation on dyspepsia which has been so freely quoted from. There are no doubt thousands suffering from functional indigestion due to causes easily understood and often removable. Some bring it upon themselves by errors of diet and neglecting the chief antidotes of the disorder, air and exercise. Others are compelled to live lives that favor indigestion and are unable to procure the air and exercise necessary to the preservation of health. Worry is, indeed, a potent cause of dyspepsia; it may be said to be the main cause among those women who are of a highly strung, nervous disposition. The advice may be given to all not to be led astray into taking all kinds of drugs. There are a few which are indicated and a sufferer, under the care of his physician, will soon discover those that suit him. If, however, he or she develop the habit of flying to every drug that is advertised, it will not be long ere such a person becomes a chronic dyspeptic.

BACTERICIDAL SERUM IN DIPHTHERIA.

While the therapy of diphtheria has made wonderful progress since the introduction of a specific antitoxin, no such progress has taken place in the prophylaxis of this disease. One difficulty in the way consists of the fact that virulent bacilli may remain a long time in the throats of patients afer recovery from the disease; the specific antitoxin in neutralizing the poisons produced by the bacilli during the clinical period of the affection affects but little the organisms themselves. These "bacilli carriers" form foci, therefore, spreading the disease by contact with others. While isolation in special hospitals is maintained until the complete disappearance of bacilli from the throat, this is not always possible in private practice, and in any case involves an irksome limitation of the patient's liberty during convalescence. The introduction of a specific remedy acting upon the bacilli themselves would be warmly welcomed by the profession in general, and health officers especially.

Such a remedy in the form of a specific serum was prepared by Wassermann in 1902, and has since been tried by several observers, one of whom, G. B. Fleischer, communicates his results in *Russkii Vrach* for September 12, 1909. This experimenter manufactured a specific serum by immunizing dogs with diphtheria bacilli of graded virulence and then used it in the form of tablets, comparing its effects with simple swabbing of the pharynx with a solution of bichloride in glycerin and water. He found that the latter method differed very much in its effectiveness, depending upon the shape of the tonsils, those with numerous irregularities protecting the bacilli from the action of the antiseptic. On the other hand, patients treated with the specific serum in the form of tablets became free from bacilli in a short time, quite without any relation to the anatomical peculiarities of the lymphatic apparatus of the pharynx. The quarantine period after recovery from disease was shortened in their case to from two to five days, while the patients treated by swabbing with antiseptic solutions harbored bacilli from one to three weeks.

The two objections to the use of this serum consisted in the difficulty and expense of preparing it and in its rapid deterioration. The gain in shortening the period of quarantine seems to have been large enough, however, to encourage the manufacture of serum on a commercial scale, as has been done recently with other products of like character, such as antigonococcic and the antistreptococcic sera. The community certainly can derive nothing but benefit from shortening the quarantine period in contagious disease, in respect to both the expense of isolation and the prevention of the spread of disease.

THE PRACTITIONER AND HIS TUBERCULOUS PATIENTS.

An editorial writer in a recent issue of the *British Medical Journal* calls attention to the lack of mutual understanding which often exists between the physician and his tuberculous patients, especially those of the "open" type, that is, those who are voiding bacilli and are potential sources of infection. Patients of this class, the writer says, are frequently kept in complete ignorance of their disease, and even their relations or those who live with them are kept uninformed of the true state of affairs. No doubt in these cases the doctor is acting upon the principle that the patient should be spared the distress of learning that he is a consumptive. But after a period of private treatment the patient seeks entrance to a special or general hospital to the wards of which only early cases are admitted, and there finds out the true state of affairs. Can the family attendant, asks the writer quoted, wonder for a moment how it is that the net result is his discomfiture and undoing? The hospital physician is in a difficult position, for he is obliged to contradict the practitioner who has had charge of the case for so many months.

The remedy for this is simple, but it entails some trouble on the part of the practitioner, and in some cases fresh study by him regarding the developments which have taken place in hospital management and in sanatorium treatment. So long as hospitals, dispensaries, and sanatoria are conducted on their present lines, the general practitioner must realize how much is being done by them to check the tide of the disease detect it in its earliest stages, and treat it on rational lines. The trouble is often with the practitioner educated years ago, not one of wilfulness, but one of ignorance. Twenty years ago tuberculosis of the lungs was not taught so far as regards the incipiency of the disease. The student was presented with the clinical picture of a full-fledged case. And even now the medical schools as a class are hardly tuned up to the demands of the hour. The use of the microscope is

a *sine qua non* in the diagnosis of the incipient case. But even before it reveals the presence of the bacillus, modern methods of examination will, if faithfully and persistently applied, reveal the true state of affairs.

Here in New York little fault can be found with the practitioners of the present day; nevertheless any one who examines candidates for admission to an institution for tuberculosis can but be impressed with the extent to which the disease will often have progressed without its true nature having been recognized.

The Hookworm Commission.

The announcement that Mr. John D. Rockefeller has given a million dollars to start the fight against uncinariasis in the South comes as an assurance that the hope expressed some weeks ago in these columns that an organized effort would be made to combat the disease will be realized. However much or little the commission itself may accomplish directly the publicity given to its findings and its acts will undoubtedly be of enormous service indirectly in bringing the sanitarians and health officers of the South to a realization of what is now expected of them in the way of suppression of this evil. It is, of course, upon them that the final responsibility will rest of eradicating the hookworm, for the constitution of the commission does not hold out great promise of immediate practical results, containing as it does only one zoologist and two nonpractising physicians, with five educators, one editor, one consulting philanthropist, and two business men. It will, no doubt, collect a mass of statistics showing the wide prevalence of the parasite, emphasizing the handicap, mental, moral, and physical, with which it loads the people of the South, and exposing the utter neglect of the first principles of hygiene by most of the small farmers, white and black alike, which is the root of the evil. This is what is needed to arouse the conscience of the people and to create a public opinion, without the assistance of which health officers can never effectually enforce their regulations. There will perhaps be a few sensitive souls who, like the Methodist Bishop of Georgia, will resent Mr. Rockefeller's donation as an insult to a free people, but by the mass of sensible citizens of the South, as well as of the rest of the country, his generosity will be gratefully acknowledged, and the work of the commission appointed to administer his gift will be followed with interest and hope.

Treatment of Hydrocephalus.

There are few diseases of childhood which hold out less hope for recovery, and offer poorer opportunity for effective therapeutics than internal hydrocephalus. Due usually to a hypersecretion into the ventricles or to an obstruction of the foramen of Magendie, the nature and location of the lesions make local treatment practically impossible. Efforts have been made to relieve the pressure by ventricular or lumbar puncture, and in a few cases some temporary benefit has been obtained. This has, however, been only temporary. Mikulicz attempted permanent drainage of the ventricle with a cannula, but in practically every case meningitis resulted. Attempts to drain from the ventricle to the subdural space have been made, by Krause by means of a silver tube, and by Payr by the use of a section of vein, but the results were no better. The latest addition to the list of operations for hydrocephalus appears in an article by von Bramann in the *Deutsche medizinische Wochenschrift* for September 23, 1909. Acting on the suggestion of Anton of Halle, a. S., the author attempted to make a permanent opening between the ventricle and the subdural space. The technique consisted in trephining near the midline and just behind the coronal suture in older children, and opening the anterior fontanelle in infants. The dura was opened wide, a tenaculum passed down the longitudinal fissure, and the cerebrum slightly retracted, care being taken to avoid the veins. A slightly bent cannula of a diameter of two to three millimeters was then passed between the brain cortex and the dura mater to the falx, and the carpus callosum was carefully punctured. After the ventricular fluid had been drawn off the cannula was moved forward and backward in order to widen the opening. The cannula was then withdrawn, the dura stitched up, and the skull cap closed, the intraventricular fluid pressure being trusted to keep the channel open. Von Bramann has performed this operation in eight cases of hydrocephalus. Some of the children died shortly from pneumonia or other infections not associated with the operation. Several, on the other hand, survived the operation and at the time of the report not only were living, but showed decided improvement in both nervous and mental condition. This operation would seem to be based on a sound physiological foundation. If the channel made through the corpus callosum remains open it should relieve the pressure produced by the obstruction of the foramen of Magendie, and it has the added advantage of leaving a closed wound in the skull, and no foreign body in the brain. The effect of the injury to the corpus callosum remains to be seen.

Microorganisms in Acute Anterior Poliomyelitis.

Infantile paralysis has recently attracted a great deal of attention in and about New York city by the occurrence of an extensive epidemic in the year 1907 and of a smaller one during the past summer. These epidemics are very suggestive of the infectious origin of the disease, as indeed is the clinical picture showing in its first stage vomiting, fever, intestinal disturbances, etc., similar to those seen in other infectious diseases. The most striking element of the disease, the flaccid paralysis, is really a consequence of the destruction produced during the acute stage rather than an independent symptom. Recently, original work has been done in this country in tracing the infective character of the affection, and in one case at least the transference of the disease to a monkey by the injection of an emulsion of the spinal cord of a child dying of poliomyelitis has been successfully accomplished. In connection with this a short preliminary communication published by Potpetschnigg in the *Wiener klinische Wochenschrift* for September 30, 1909, is of interest. The author had the opportunity of observing twenty-two cases of the disease in the acute stage, an epidemic having been present in his neighborhood. Lumbar puncture was performed in fourteen of these cases, and in all the spinal fluids obtained Gram-positive micrococci, usually of diplococcus character, were found. The organisms were discovered independently by several physi-

cians of a hospital and proved to agree well in cultural and structural characteristics. In one patient, moreover, brought to the institution in the first day of the illness, Dr. Potpetschnigg succeeded in recovering a similar organism from the blood. Further work is in progress in determining the rôle of the organism in the disease. The author used bouillon as a medium, employing large quantities of spinal fluid in making cultures and carrying on the growth of the organisms on agar plates after one day's growth in bouillon. It may be worth while for American observers to follow the same technique whenever the disease is recognized in its earliest stages. The results of such work here and abroad will certainly be awaited with interest.

News of the Week.

The Herter Lectures at the University and Bellevue Hospital Medical College will be given this year by Professor Otto Cohnheim, of the University of Heidelberg. The lectures begin on Monday, December 6, at 4 P. M. and continue daily throughout the week. The subject is "Enzymes and their Actions." Those interested are cordially invited to attend.

Investigation of Contagious Diseases in Massachusetts.—In an investigation as to the needs in Massachusetts of a State institution for the care of town paupers with contagious diseases, reports from 128 cities and towns show that there are at present 1,088 such persons dependent upon town charity, while there are still 97 towns to be heard from. These figures do not include tuberculous paupers.

A Commission for the Eradication of Uncinariasis.—There was organized, October 26, at the suggestion of Mr. John D. Rockefeller, who has donated the sum of one million dollars to carry on the campaign, a commission for the investigation of the hookworm disease in the South. This commission is composed of Dr. William H. Welch, Dr. Simon Flexner, Dr. Charles W. Stiles, Dr. Edwin A. Alderman, Dr. David F. Houston, Prof. P. P. Claxton, J. Y. Joyner, Walter H. Page, H. B. Frissell, Frederick T. Gates, Starr J. Murphy, and John D. Rockefeller, Jr.

Low National Death Rate.—The death rate for 1908 in the registration area set aside by the Census Bureau for tabulation purposes was 15.3 per 1,000 population, the lowest figure yet recorded. In rural districts covered by the tabulation the rate was slightly lower, averaging 14 to the 1,000 inhabitants. During the same period the death rate for England and Wales was 15.7 per 1,000. The total number of deaths returned for the year 1908 in the registration area was 691,574, while for the preceding year it was 687,034. This apparent increase of 4,540 is explained by the fact that during 1908 two new States, Washington and Wisconsin, were added to the registration area. The month of maximum mortality in 1908 was January, with 67,763 deaths, and that of minimum mortality was June, with 49,701 deaths. The death rates of the individual States vary from 18.4 for California to 10.1 for South Dakota.

New York's Health.—During the week ending October 23 there were 1,346 deaths in the city, and the rate, 15.38 per 1,000, was greater than the death rate for the same week last year, which was 14.48, representing 1,228 deaths. The largest increase was in death from heart disease, there being 162 cases, as against 123 a year ago. There was also an increase in deaths from typhoid fever, pneumonia, diarrheal and Bright's diseases, but only 145 deaths from tuberculosis, as against 156 last year.

French Birth Rate Low.—Vital statistics for the first six months of the present year show an excess of deaths over births in France of 28,205.

Antituberculosis Campaign in Factories.—An active fight against tuberculosis is to begin in the factories of Rhode Island. It will take the form of circulars of instruction placed in every pay envelope, the taking up of individual cases of tuberculosis of threatening symptoms by the local organizations, the posting of wall placards of instruction, and the giving of noon-hour or evening lectures. The factory committee of the Rhode Island Antituberculosis Association is in charge of the campaign. The State Association and the Providence Board of Trade, in cooperation with the State Board of Health, are arranging with factories throughout the State to carry out the new plans.

Increased Appropriation for Tuberculosis.—The New York Budget adopted by the Board of Estimate, October 29, allows for an increase of $263,500 for tuberculosis work.

Cattle Laws in Illinois.—Beginning November 15, all certificates of tuberculin tests for cows in the State of Illinois, filed with the State Department of Health must be approved by the State Veterinarian before they will be accepted. The State Veterinarian will appoint deputies throughout the State who will work under his supervision and will file their reports with him. The State Veterinarian has ruled that these deputies must report all the tests yielding positive as well as negative, results. It is the intention of the State to brand all animals giving a positive reaction. This will be done by punching the letter "T" in the right ear.

American Hospital in Paris.—The American Hospital built and equipped through the generosity of the American colony in Paris was formally opened October 28 in the presence of the U. S. Ambassador White, Minister of Education Doumergue, who represented the French Government; members of the Board of Governors, and the medical staff. The hospital, the need of which has long been felt, is beautifully situated at Neuilly, and is surrounded by spacious grounds. It contains twenty-five beds, many of which have already been endowed. Among those who have thus contributed are J. P. Morgan, W. K. Vanderbilt, and Miss Helen Gould.

New Hospital for Vancouver, Wash.—A new five-story hospital to be known as St. Joseph's Hospital is being constructed in Vancouver, Washington, at the cost of $125,000. The building will be 136 x 48 and 76 feet high. There will be 128 rooms, and also a solarium at each end.

The Carrol College Infirmary and Dispensary has been opened in Milwaukee in connection with the medical department of the college.

The Presbyterian Hospital of Omaha has recently moved into new quarters in the former home of Bishop Worthington. The new hospital has private rooms for forty patients. With the view of future extension an acre of ground surrounding the hospital has been obtained.

Bequest to Yale Medical School.—By the will of Dr. Levi S. Shoemaker, of Wilkesbarre, who

died recently in Germany, the medical department of Yale college will receive $600,000 upon the death of Mrs. Shoemaker.

Tuberculosis Night Camp.—The new department at the New York Throat, Nose, and Lung Hospital, 229 East Fifty-seventh street, for the treatment of tuberculosis at night, was opened on Wednesday evening of this week. The department will be a night camp of those in the early stages of the disease who cannot afford to leave the city, and have to work in the daytime. It is in a remodeled building next to the hospital.

Charitable Bequests.—In the will of the late Jane G. Phelps the following hospitals were remembered: Presbyterian Hospital of New York, $10,000; Tarrytown Hospital, $5,000; Lincoln Hospital and Home, Manhattan, $5,000. Chicago Charities Benefited $382,000 by the will of the late Mrs. Nelson Morris. Of this amount, $300,000 is left for the founding of a convalescent hospital or home for children. This bequest is made preferably to Michael Reese Hospital. The Children's Memorial Hospital receives $5,000; Michael Reese Hospital, $10,000; The Chicago Lying-In Hospital and Dispensary, $2,500; The Chicago Home for Incurables, $5,000, and the Chicago-Winfield Sanatorium, $5,000. At the twenty-fifth anniversary of the Montefiore Home in New York the announcement was made of gifts aggregating $101,500. The chief presents were from Messrs. Jacob H. Schiff, $50,000; Murray Guggenheim, $25,000; Mortimer L. Schiff, $10,000; Felix M. Warburg, $10,000; Paul M. Warburg, $5,000; Isidor Straus, $1,000, and Dr. Morris Loeb, $500. By the will of the late Miss Anna J. Van Reed of Reading, Pa., the sum of $13,000 is bequeathed to the Medico-Chirurgical Hospital of Philadelphia.

The Southern Medical Association will hold its annual meeting in New Orleans on November 9-11. The officers of the association are *President*, Dr. G. C. Savage of Nashville, Tenn., and *Secretary and Treasurer*, Dr. Oscar Dowling of Shreveport, La.

The Minnesota State Medical Association, at its annual meeting held at Winona, recently elected the following officers: *President*, Dr. W. A. Jones of Minneapolis; *Vice-Presidents*: Dr. W. F. Dimitt of Red Wing, Dr. Hugh F. McGaughey of Winona, Dr. G. W. Bray of Biwabik; *Secretary*, Dr. Thomas McDavitt of St. Paul; *Treasurer*, Dr. R. J. Hill of Minneapolis; *Board of Counsellors*, Drs. E. A. Hensel of Alexandria, F. A. Knight of Minneapolis, and F. A. Dodge of Le Sueur. The next annual convention will be held at Minneapolis, October 6 and 7, 1910.

The Kentucky State Medical Association on October 21 chose Lexington as the place for the next annual meeting, and elected the following officers for the ensuing year: *President*, Dr. I. E. Wells of Cynthiana; *Vice-Presidents*, Dr. P. H. Stewart of Paducah, Dr. J. O. Carson of Bowling Green, and Dr. J. S. Lock of Louisville; *Delegates to the American Medical Association*, Dr. W. B. Boggess of Louisville and Dr. B. F. Van Meter of Lexington.

The Southern California Homeopathic Medical Society at its annual meeting at Los Angeles elected the following officers: *President*, Dr. W. J. Hawkes; *Vice-Presidents*, Dr. M. B. Campbell and Dr. F. Estes; *Secretary and Treasurer*, Dr. F. S. Barnard.

The Ionia County (Mich.) Medical Society at its annual meeting held at Ionia, October 18, 1909, elected officers for the ensuing year as follows: *President*, Dr. George A. Stanton of Belding; *Vice-Presidents*, Drs. C. C. Dellenbaugh of Portland, F. A. Hargrave of Palo, W. J. Wilkinson of Orleans, F. B. Morse, Lake Odessa; *Secretary and Treasurer*, Dr. C. S. Cope of Ionia.

The Associated Physicians of Long Island held the thirty-fifth regular meeting at Rockville Centre, Saturday, October 23, under the presidency of Dr. Frank T. De Lano of Rockville Centre. Papers were read by Dr. Harris A. Houghton of Bayside, L. I., Dr. H. A. Alderton of Brooklyn, and Dr. Roland Hazen of Brentwood.

Obituary Notes.—Dr. Benjamin Harrison Kidder, U. S. N., retired, of Malden, Mass., died at his summer home in Edgartown, Mass., October 26, 1909, aged 73 years. Dr. Kidder was a native of Massachusetts and entered the United States Navy from that State as an Assistant Surgeon in September, 1861. He was first attached to the gunboat *Marblehead* in the South Atlantic Blockading Squadron from 1862 to 1864, and then went to the frigate *Colorado*, the flagship of the North Atlantic Squadron, on which he served throughout the remainder of the Civil War. He afterward served on the *De Soto*, *Terror*, *Ossipee*, *New Hampshire*, *Wyoming*, *Wabash*, and the *Powhatan*. He was promoted to the rank of Surgeon in 1868 and became a Medical Director of the Navy in 1893. Five years later he was placed on the retired list with the rank of Rear Admiral.

Dr. Samuel R. Elliott of New York died October 26, 1909. He was a graduate of Columbia University and a veteran of the Civil War. Dr. Elliott was the son of one of the first men to practise ophthalmology in this country.

Dr. John M. Eaton of Harvard, Mass., died at his home, October 22, 1909, aged 77 years. He was a graduate of the Harvard Medical School in 1850, and served as army surgeon in the Civil War.

Dr. James W. Ryder of Boston, Mass., died at his home, October 21, 1909, aged 41 years. He was a graduate of the Dartmouth Medical School in 1896, and was a member of the Suffolk County Medical Society, the Massachusetts Medical Society, and the American Medical Association.

Dr. William Cooke Steedman of Lagrange, Ky., died October 21, at Louisville, aged 40 years. He was a graduate of the Louisville Medical College, in 1899, and was a member of the Oldham County Medical Society and the Kentucky State Medical Association.

Dr. William G. Terwilliger of Brooklyn was killed in an automobile accident on October 31, 1909, near Long Beach. Dr. Terwilliger was 38 years of age. He was a graduate of the College of Physicians and Surgeons of Columbia University, 1894, and was a member of the Medical Society of the County of Kings and of the New York State Medical Association.

Dr. George B. Dowling of Tarrytown, N. Y., died in New York, October 30, 1909, aged 42 years. Dr. Dowling was a graduate of the New York Homeopathic Medical College in 1889.

Dr. Josiah Cadmus of New York died at his home, on October 28, 1909, aged 90 years. Dr. Cadmus was a graduate of the College of Physicians and Surgeons of New York and had practised in the city for over sixty years.

Correspondence.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

OPENING OF MEDICAL SOCIETIES—EXHIBITION OF CLINICAL CASES—OVERSTRAIN OF HEART—INDIAN CONFERENCE ON MALARIA—DANGERS OF DRY SHAMPOO—ARTIFICIAL FEEDING—OBITUARY.

London, October 15, 1909.

This has been a very busy week. The medical societies have opened with renewed vigor after their recess and questions of interest in relation to the public health have been discussed by several nonprofessional associations. The Royal Society of Medicine opened its session on Friday by an interesting exhibition of cases in the Clinical Section, and on Tuesday followed up with a paper in the Surgical Section by Mr. Godlee on "Prognosis in Some Diseases of the Lungs and Pleura Usually Treated Surgically." In the meantime the Medical Society of London opened its session on Monday evening with the president's address, followed by a paper on "Perforation of the Small Intestine," by Mr. Hugh Leet. On Wednesday the Hunterian Society had its first Hunter Lecture, by Dr. Martin, on "Infective Processes in the Intestine." To-day we have Professor Keith's demonstration at the Royal College of Surgeons, the Electrotherapeutic Section at the Royal, and at the Tropical Society a discussion on sleeping sickness. In the clinical exhibition just mentioned Dr. H. W. Bayley gave a demonstration of the *Treponema pallidum* in syphilitic lesions, of the *Spirochæta dentium* in carious dentine, and of the *Spirochæta refringens* in balanitis. Dr. Bunch showed a man with *Mycosis fungoides* of twelve months' standing who had improved under arsenical treatment (hypodermically) and *x*-rays locally. Dr. Rolleston showed a case of inky pigmentation of the mouth and marked freckling of the face in a man of 25 admitted for pernicious anemia with enlarged liver and spleen. The number of red globules varied from 1,515,000 to 3,015,000, the percentage of hemoglobin from 40 to 76, the leucocytes from 2,960 to 4,000. Only one nucleated red corpuscle had been seen.

Mr. A. Carless showed a man from whom he had removed the entire upper jaw, part of the molar bone, the floor of the orbit, the nasal process, and ramifications in various directions of a growth which proved on microscopical examination to be an epithelial odontome. The above operation relates to the left side. The patient did well, but returned five months after with a tumor on the right. This maxilla was therefore removed, leaving the orbital plate, and the patient has continued well for twelve months. He has been fitted with a denture and can masticate soft food and does not seem to suffer much inconvenience. There is but slight deformity—so slight that the president, Mr Pearce Gould, said he never expected to see so little in such a case. He had not had one so successful in this respect.

Mr. Sherrin showed a case of Meckel's diverticulum containing calculi producing symptoms thought to be appendicular. On opening the right iliac region he found a sac connected with the ileum containing the calculi. On removal it was 4 inches long, partly closed at the attached end by a valvular opening, filled with irregular brownish brittle concretions, composed of calcium oxalate and cholesterine, with a trace of bile pigment. Uneventful recovery followed. Four similar cases have been recorded. Dr. A. E. Garrod thought the concretions looked like gallstones. If bilirubin were present that would necessarily be so. Cholesterin would be compatible with any mucous membrane inflamed and occurred in the urine in cystitis.

Dr. E. I. Spriggs showed a boy of 16 with rheumatoid arthritis and enlarged spleen and other glands. The disease began at the age of 10 and progressed till most joints were affected. The vertebral, temperomaxillary, and sternoclavicular had escaped. The axillary, epitrochlear, supraclavicular, and inguinal glands were enlarged; the spleen reached below the costal margin for about an inch. Dr. A. E. Garrod remarked that he did not think the disease was different in children and adults, the more general reaction in children being a common modification in accordance with age. Dr. Rolleston said a Continental observer had reported that he had isolated an organism from the glands in such cases, both in children and adults. Sir Dyce Duckworth said such cases (which were described by Dr. Still) he had himself always looked upon as a blend of the strumous and rheumatic diatheses. A number of other interesting cases were shown at this meeting.

Professor Theodor Schott of Nauhaim gave an address on Monday at the West London Hospital. He spoke in English and his subject was "Acute Overstrain of the Heart," as to which he described his renewed research. He began by referring to his experiments reported to the Vienna Congress, 1890. Their object was to decide whether bodily overstrain could produce perceptible changes in the normal heart, and if so what was the nature of the changes. He engaged young men free from any abnormal cardiac condition to wrestle together until a high degree of dyspnea was produced with the great muscular strain. By such experiment he found that severe overstrain led to difficulty of breathing and that the heart underwent a greater or less degree of dilatation, which, however, he thought should be regarded as temporarily abnormal, but not as pathological. These observations had been confirmed by *x*-rays. Chronic overstrain, he proceeded, was the result of a repetition of excessive muscular efforts. This view had also been confirmed by enlargements of the heart found in cyclists and skirunners. Last year he had renewed his researches, and the first question he put to himself was whether a healthy heart muscle would become hypertrophied from excess of work. The answer was affirmative, and he also believed such work would cause dilatation. It was physiologically established, he remarked, that simple labor could lead to hypertrophy. Examples were many that excessive indulgence in athletics had led to chronic overstrain, even in those who had not added immoderate indulgence in tea, coffee, tobacco, or alcohol. Strong emotion, fright, and shock were also likely to produce serious effects on the heart, and medical men had plenty of opportunities of observing how anxiety and mental worry often impaired its muscles and nerves. The dilatation on mountain climbing he considered was only an accumulation of blood in the cavities. The deleterious effects of cycling were seen in nearly all experiments, and cases of heart trouble following racing occurred in large numbers. Zuntz and Schumberg found that heavily accoutred soldiers who had climbed high mountains had suffered from dyspnea, and on examination they detected a dilatation of the cardiac diameter of between two and three centimeters. Admitting divergences between some results, he said they were easily explained, for, according to the researches of later years, the construction of the heart was that of the most perfect motor with which we were acquainted, so that it was capable of answering to the smallest stimulus with a maximum development of power. It had, too, the faculty of adapting itself to changed demands, for the dog's heart would take up six times the ordinary quantity of blood and contract again completely. The human heart, in its muscular apparatus and its vascular system, had all kinds of compensatory arrangements. But nevertheless, he wished to point out that every physician who saw large numbers of heart cases could easily confirm his statement that in persons previously normal, solely through the most different forms of overstrain the heart might be brought, firstly, to acute dilatation, and later, through repetition of the cause, to permanent dilatation, with all its consequences.

The Indian Conference on Malaria was opened at Simla on the 12th and will continue until the 18th inst. Lord Minto, in welcoming the members, said it seemed to him desirable to have an assemblage possessing full knowledge of all local conditions, and that local authorities should have a joint plan of campaign, so with this view he had convened this Imperial Conference. It was with the utmost humility as a layman that he addressed that galaxy of expert talent, but the cruel epidemic of last year impressed on the public the magnitude of the question the Government had to deal with. Last year the deaths were a million over the average, believed to be largely due to malaria. Scientists assured him much of this appalling suffering and economic loss could be prevented. The chief problem of the conference was to confirm this and to show how. He trusted their deliberations would confer a great boon on India, and though a campaign would have to be long and hard-fought, he opened the conference in the firm belief that it would eventually be crowned with success.

Colonel Leslie, Sanitary Commissioner of the Gov-

ernment, then spoke. He stated that about twenty deaths per 1,000 in India were ascribed to fever, but it would be exceedingly hard to assign the proportion of these due to malaria. He dealt at length with questions relating to the extermination of mosquitos and with the use of quinine as a preventive. As to the latter he said much evidence had been collected to show that regular doses of quinine were a nearly complete preventive, and he suggested the establishment of provincial agencies for its distribution and also committees for inquiring into the causes of death and the distribution of malaria. The members of these committees would confer in Simla each autumn with the Scientific Committee of the Indian Government.

A charge of manslaughter in consequence of a death under the so-called dry shampoo has occupied attention since July 12, but has at last been withdrawn and no blame imputed to any one. It is of medical interest, as the liquid used was chiefly composed of tetrachloride of carbon, a substance about which the expert witnesses did not possess much information. It seems clear that the liquid had been applied as a hair wash for a long time without accident, but in the fatal case the lady was thought to have fainted and laid on the floor—thus depriving her of her last chance of revival; for the vapor of tetrachloride of carbon is very heavy, and a more powerful anesthetic than chloroform. Medical aid was called in, but the patient was dead. On the withdrawal of the charge, counsel stated that the prolonged proceedings were taken to warn hairdressers and the public of the great dangers of this process of dry shampoo. Curiously enough, two other deaths from an explosion occurred just after the close of the inquiry. In these last the tetrachloride was not used, but petrol, and the vapor seems to have been permitted to come into contact with gas—the natural result being explosion and a fire. But the inquiry into this is not concluded. The lesson is plain enough, that such dangerous substances ought not to be so used, or, indeed, sold to those who know nothing about them. In the former inquiry another medical question was raised: What is status lymphaticus? The pathologist who made the post mortem said there were indications of this condition. On the other hand, Colonel Lawrie, president of the Nizam's Chloroform Commission, who was present at the post mortem, and acquainted personally with the deceased lady, deposed that she was in perfect health when he saw her twelve days before the death. Further, he did not think status lymphaticus a pathological condition. Certain indications of it were pointed out to him at the autopsy, and they might be; but to him they appeared mere peculiarities. I think there are many who regard the existence of status lymphaticus as doubtful, and perhaps the point may lead to further investigation.

Artificial feeding threatens a winter of excitement. An inquiry has been granted by the High Court as to whether undue force was used in feeding some of the suffragettes. Yesterday two others were released after two days' fasting, and are now setting up an agitation against the injustice of not allowing them to be "tortured by forced feeding," like their dear comrades, though they tried to make their offenses just as serious. In opposition to these we have the "Woman's Anti-Suffrage League," formed to protest against their sex having a vote. They have prepared an active campaign to carry on through the winter by means of lectures, debates, and speeches in the chief towns. They will teach that respectable women do not demand the vote and hate violence; that to give a vote in response to violence would be disgraceful; that to condone lawbreaking on the plea that it is "political" would be a political crime; that criminals who act as lunatics bent on suicide are properly treated as such; that to pretend the doctors are cruel in using the stomach pump is a gross "political falsehood," and they are certain that artificial feeding is safe in the hands of the doctors.

Dr. G. J. Cooper, M.P., died on the 8th inst., aged sixty-five. He was seized with paralysis in the House of Commons the previous day and never rallied. He was a strenuous worker, had spoken at many meetings during the past month, and been his own agent at the recent revision court, and his own surgery was the meeting place of his party. It was thought he had overworked. He was educated at Leeds, Manchester, and London University College. He was formerly resident at Poplar Hospital for Accidents and Bristol Infirmary. He settled in Bermondsey, and became so much esteemed that he was elected a Member of Parliament for the division at the last election. The present session of Parliament has been a most exacting one in the Commons, and Dr. Cooper was always assiduous in his attendance. No wonder that this, with the care of an active practice, was too much, and the breakdown was the consequence.

OUR BERLIN LETTER.

(From Our Regular Correspondent.)

CARE OF INFANTS—NEED OF MATERNITY HOSPITALS IN GERMANY—EFFECT OF WALKING TOURS ON SCHOOL CHILDREN—STATISTICS OF PHYSICIANS IN GERMANY.

BERLIN, September 10, 1909

AMONG the various medical occurrences of Germany during the past summer there was one event specially worthy of a report and of especial interest—the First German Congress for the Care of Infants. This congress, which was honored by the especial patronage of the Empress, was held in Dresden. The first speaker was Dr. Keller of Berlin, who described the present situation of the care of infants, collected into one whole the various organizations, and explained their development.

Three speakers discussed lying-in hospitals, care of the pregnant, and infant homes as means of combating mortality. Dr. Dietrich of Berlin, of the Prussian Ministry of Public Instruction, reported that one-ninth of all the infants dying in the first year died in the first four days of life and one-fifth in the first month. Of a million births annually in Prussia four-fifths of the mothers were attended by midwives only. For this reason the most important means in the fight against the high infant mortality was the instruction of the midwives in relation to care and feeding of infants. As many unmarried, dishonorable mothers were homeless for the last months of pregnancy, and through lack of space were often discharged from the hospitals within six or seven days after the birth of their children, it was of pressing importance to Germany that more lying-in homes be created. In Berlin there were in all only three hundred beds in maternity institutions. Protection and care during the early months was necessary to give the child its proper foundation. The maternity institution must be the medium of giving to the people object lessons in the care and feeding of infants.

Dr. Salge of Göttingen spoke on the necessity for and the regulation of maternity hospitals. For legitimate children of the working classes also the maternity hospitals, by appropriate nursing, offered the best surety for proper development. The instruction of the midwives in the artificial feeding of infants and the treatment of illnesses was a point to be considered. This was the province of the physician.

Dr. v. Frangué of Giessen presented some interesting statistical material. In Germany ten thousand mothers died annually as the result of childbirth, seven thousand of them of puerperal sepsis. To this number must be added at least fifty thousand more who, on account of serious illnesses resulting from pregnancy and labor, were unable to nurse their children. If the hospitals were to supply maternity facilities for all the pregnant women who really needed it, over two hundred thousand mothers would have to be delivered each year. To-day this happened with only one-fifth of the mothers. If these measures against infant mortality should cost much money, it must be remembered that the healthier the resulting children the less need there would be for hospitals.

Dr. Meier of Munich spoke on measures to promote nursing of infants. A complete set of statistics for the entire German Empire was much needed. Instructive conclusions could be drawn from statistics of isolated divisions. For example, in one ward where 90 per cent. of the infants were breast-fed the mortality was 10 per cent., while in another ward, with but 30 per cent. of breast-fed infants, it was 40 per cent. The situation of the children of the wet nurses was especially sad. It should be required by law that the mother nurse her own child at least two months before giving it up for a strange infant. Above all things, the women of the cultivated classes should set the example by nursing their own infants. The universal adoption of a motherhood insurance was a pressing need.

Dr. Roeder of Berlin presented an interesting report at the Union of the Berlin School of Physicians on the hygienic results of walking trips. He examined

school children before and after a walking tour to see whether the favorable results of such a trip were only subjective, or whether objective benefit occurred. Fifty-six children were sent on walking trips in three groups, each under the leadership of a teacher. The children walked on an average ten to twenty miles a day. For breakfast they were given coffee, milk, and white bread, during the day bread and butter, and in the evening a warm dinner. As the result on body weight one series of well-nourished, strong children did not change weight during the six days' tour. A small number either lost weight or gained from one to three pounds. It was of interest, however, that during the following three months fifty of the fifty-six children gained weight from three to twenty-two pounds. From this it would appear that the violent muscular exercise stimulated the organism to increased metabolism and more rapid growth. Especially of interest is the comparison of nine girls who took the tour with twelve from the same school who had not been on the trip but had taken vacations at the same time. The girls who had walked gained 6.7 pounds during the next three months; those who had not walked only 4.8 pounds.

Drs. Reuss and Rosner of Stuttgart have presented some interesting statistics on the number of physicians in Germany. Whereas the population of Germany in 1885 was in round numbers 46,000,000, in 1907 it was 61,000,000, an increase of some 30 per cent. The number of physicians in 1885 was about 15,000, in 1907 30,000. The increase in physicians during this time was therefore proportionately more than three times greater than the increase in the population. While in 1885 about 4,000,000 persons were insured against sickness and paid 9,000,000 marks for medical attendance, during 1907 in the neighborhood of 11,000,000 persons paid 63,000,000 marks. From this it will be seen that the physicians honorarium has increased sevenfold during this period, while the number of the insured has increased less than threefold. Furthermore, since 1885 the relations of the insured have been supplied with medical treatment in ever increasing numbers without the statistics mentioning these relations in the list of honoraria received. Finally, it is undoubted that since 1885 the demand for medical treatment on the part of the insured has increased greatly.

THE EIGHTY-FIRST CONGRESS OF GERMAN NATURALISTS AND PHYSICIANS.

(From Our Vienna Correspondent.)

EXUDATIVE DIATHESIS—FRACTURE OF THE HIP—TENDON TRANSPLANTATIONS—THE SOURCE OF THE CARDIAC POWER—TREATMENT OF OBESITY—DIABETES AND TUBERCULOSIS—ESTIMATION OF NUTRITIONAL STATES—EARLY TUBERCULOSIS OF THE SKIN—THE ABILITY TO NURSE.

SALZBURG, September 25, 1909.

IN the presence of a great assemblage there was opened on September 19, 1909, in the old university city of Salzburg, the Eighty-first Congress of the German Naturalists and Physicians, in which participated the most prominent savants of Germany and Austria. Of especial importance were the papers of Professor Czerny on the exudative diathesis, scrofula, and tuberculosis, and in the surgical section by Professors Lorenz and Hacker on operative and bloodless orthopedic treatment.

Czerny stated that a special condition had induced him to work during the last few years on the subject of the exudative diathesis. This was the senseless and one-sided feeding of many children on milk and eggs, which, in the presence of the predisposition, produced the symptoms of this disease. Constitutional anomalies as the exudative diathesis were inborn, showed themselves in early infancy, and consequently must be studied at that period. Though not evident at birth, the first nourishment—even breast milk—produced symptoms. Usually these were not marked until the end of the first year, when a digestive upset produced the symptoms of the congenital disease. Besides digestive disturbances, infection processes, vaccination, or the use of tuberculin might be the exciting cause of the outbreak. Measles and acute tuberculosis were especially liable to produce symptoms of the condition. This last combination produced the picture formerly called scrofula. Dietary treatment cleared up the symptoms of the diathesis, but the tuberculosis remained. This was responsible for the idea that scrofula was a tuberculous process.

Professor Lorenz, in the surgical section, spoke on the ambulant extension treatment of fracture of the neck of the femur. Apart from the possibility of a fatal result, the fracture of the hip was of all fractures one of the most to be feared, as it belonged to the class with the most severe after effects. Aged patients were incapacitated for life, while children, adolescents, and adults were offered the sad prospect of a life of invalidism. It was a traditional error that fracture of the neck of the femur was a prerogative of the aged. On the contrary, it was very common during adult life and not rare in children. The most common form was the fracture of the head of the femur in the epiphyseal line in adolescence. This was not well known, as the condition had been considered a primary disease, coxa vara. The combination of fracture of the head and dislocation was often mistaken later for a healed fracture of the neck. The author had treated all such cases as fractures, with unexpectedly good results. As this separation of the cap of the head of the femur closely resembled in symptoms fracture of the neck, Lorenz had used his method in treating both classes of cases in children and adults. The aged were not included. In order to replace the fragment exactly the author did not trust the uncertain method of extension in bed, but corrected the deformity manually under general anesthesia and fixed it by properly immobilizing the legs in a bandage, which enabled the patient to walk around without danger of displacing the fragment. The correctness of the position could be controlled by the *x*-ray.

Professor v. Hecker of Gratz described two new operations for the autoplastic repair of both extensor and flexor tendons of the fingers. The first operation applied to the extensors, in those fingers which were supported by two tendons bound together, the thumb, index, and little fingers. One of these tendons was dissected out in the neighborhood of the wrist, brought forward, and used to join the peripheral end of the other to the last phalanx. The operation was done at one time. The operation had been carried out by the speaker in one case in which a blow from an axe had opened the first interphalangeal joint with a loss of 5 cm. of tendon, the result being complete restoration of extensor power in the finger. A skin transplantation was also done. The second operation might be applied either to the extensor or flexor surface of the finger, and for injuries on the finger itself or on the hand. It depended on using a superfluous tendon from the back of the hand. The most useful tendons for this purpose were the extensors of the index or little fingers. The operation was performed in two stages. In the first stage the appropriate tendon was found, cut across and drawn out through an incision above the knuckle and then passed down through a subcutaneous canal on the flexor surface of the proper finger, and implanted onto the terminal phalanx. In the second operation the transplanted piece was connected with the central tendon stump. The operation had been performed by the operator with restoration of function of a finger The author believed that the two methods would prove valuable. Every surgeon knew the difficulty of treating cases of injured tendons of the fingers. These methods offered more hope of proper healing than the implantations of dead material or the open tendon plastic operations.

In the internal medicine section Professor Adamkiewicz of Vienna presented an interesting paper on the source of cardiac power and rhythm. He said that the true source of the power of the heart was previously unknown. The author, on the basis of metabolic experiments on men, said that the rhythm of the heart was an immediate function of its power, and that the former was lost when the latter sank below a definite minimum, and that the power of the heart was in turn a factor of its nourishment and depended upon the chemistry of the blood. Thus the cardiac rhythm depended primarily on the chemistry of the blood and not upon any mechanical influence. An injury to the rhythm occurred as soon as the power diminished, much as a machine became irregular as its power diminished or a horse lost its stride when he was tired. He had further found in his researches that the particular source of cardiac power was the sugar in the food; that the burning of the sugar in the blood had the same significance as the burning of coal in an engine. A poverty of sugar in the human body expressed itself as a chemical lesion of the heart and resulted in cardiac weakness. This fact is not of purely theoretical inter-

est, but of practical value also. It often happens that signs of sugar starvation are mistaken for symptoms of fatty heart. If one treated these "signs of fatty heart" by removal of the fault in the diet, that is, by increase in the sugar intake, one developed the greatest likelihood of maintaining the health and life of the patient.

In the same section Professor Albu of Berlin spoke on the treatment of obesity by a vegetarian diet consisting of bread, vegetables of all kinds, raw fruit in large amounts, preserves (sweetened with saccharin or not at all), and now and then leguminous plants. Drinks with little nutritive value, as coffee, tea, mineral waters, buttermilk, lemonade, and occasionally sour milk were allowed. Potatoes also might be taken. Two to three eggs were allowed daily. The entire nutritional value of this food was reduced to one-half of that usually taken. The cure was carried on for from four to six weeks, and then twice weekly and later daily 150 grams of fat-free meat was allowed. This vegetarian diet usually produced a loss as high as twenty pounds. By this diet the feeling of satiety of the full stomach was obtained, with a relatively small nutritive value to the food.

Dr. Alfred Lustig of Franzenbad spoke on the subject of diabetes and tuberculosis, and said that repeatedly the two diseases were diagnosed in the same patients in whom a predisposition to the disease could be shown. On the one hand, a long-standing diabetes case often developed pulmonary tuberculosis, especially in young individuals; on the other hand, the children of diabetics were early attacked by tuberculosis. The author laid this connection at the door of a dyscrastic characteristic of the diabetic blood, which appeared to depend not entirely on the metabolic anomaly but also on the prolonged one-sided diet. While in young individuals the combination of diabetes and tuberculosis usually led to a rapidly fatal ending, this was not the case with old people. So also hygienic prophylactic measures enabled one to protect the children of diabetics against the onset of tuberculosis; or, at least, when it was present to weaken its character.

Dr. Karl Oppenheimer of Munich spoke of a method of estimating the nutritional condition of a patient. The circumference of the upper arm in a healthy, well-nourished individual was about 30 per cent. of the circumference of the chest, this ratio applying to child as well as to adult. The ratio of chest to arm was a constant, and was effected only by the state of nutrition. Oppenheimer proved the accuracy of this on 620 patients. Of 350 children from the poorest of the Munich population only 31 per cent. were well nourished.

In the section on pediatrics Dr. Karl Leiner and Dr. Friedrich Spieler of Vienna spoke on a disseminated skin tuberculosis resembling an exanthematous skin lesion, which they had repeatedly had opportunity to observe as the forerunner in the course of tuberculosis in childhood, and considered to be of great significance in the diagnosis and prognosis of tuberculosis of childhood, as it might be the only sign of the disease. The authors described the clinical picture of the disease, and the characteristic microscopic tissue changes of the condition, of which definite forms could be distinguished, in one of which the bacteria were very numerous, in another very hard to find, indeed.

Privat Docent Dr. K. Hegar of Freiburg spoke on the inability to nurse as the result of maldeveloped breasts. He contradicted the often-stated fact that there was no such thing as a breast which was not able to nurse on anatomical grounds. The basis of this belief lay in the fact that the recent movement among pediatrists and obstetricians had succeeded in causing many women, previously unable to nurse, to carry out that function successfully. Dr. Hegar reported the results of his own experience. Of 74 women, 25 were completely able to nurse, 21 partly capable, 22 lost their milk during the first two weeks, and 6 were never able to nurse. The cause of their inability lay in an insufficiently developed breast, especially of the gland, in malformations of the nipple, etc. For comparison and to show that at least in that region undeveloped breasts were very common, the author observed the condition of the breasts of a series of women who had never borne children. Of 94 such women, 22 had well developed breasts and nipples, 22 had good breasts but poor nipples, 21 very large breasts and poor nipples, 15 poor breasts and imperfect nipples, and 14 completely infantile type of breast.

Progress of Medical Science.

Boston Medical and Surgical Journal, October 21, 1909.

Asexualization as a Remedial Measure in the Relief of Certain Forms of Mental, Moral, and Physical Degeneration.—J. Ewing Mears refers to the various movements along the line indicated in the title of his paper and the legislative enactments which have been made in certain of the States in regard to it. Is it asking too much, he says, when the State, through carefully considered legislation, which in every detail shall safeguard the rights of the individual, seeks to protect itself against the degrading influence of the continually flowing stream of transmitted pollution which saps the mental, moral, and physical vitality of its citizens by asking the parents and guardians of the irresponsible defectives to yield their consent to the performance of an operation which in some instances may prove to be curative and in many to be palliative by abrogating sexual perversions and thus establishing conditions favorable to mental and moral cultivation, and in all, through its far-reaching result, is able to render them impotent to do harm? Failing to obtain this consent, has not the State the right to adopt such measures in the interest and protection of its citizens? Nay, further, is it not compelled so to act in the performance of its full duty to its citizens? The education of public opinion has so far progressed that to-day communities, through their appointed officers, exercise the right to deprive citizens of their liberty in order that a focus of infection may be stamped out; in epidemics of certain infections and contagious diseases the citizen is compelled to receive prophylactic treatment to render him immune, and in this way the spread of the disease is checked.

The Intravenous Use of Strophanthin in Broken Cardiac Compensation.—Three cases are reported by A. K. Stone, who says that strophanthin is an amorphous or crystalline powder, soluble in both alcohol and water. Each milligram of the substance has the potency of 20 frog units—that is, power to stop the hearts of 20 frogs of similar size and under similar conditions and with all other precautions that have to be observed in dealing with such a variable unit as a living animal. The dose for an adult who has not been taking any other form of digitalis or strophanthus, and especially in all those cases in which sudden collapse has occurred, should be one milligramme. This will give immediate and powerful results and will not have to be repeated for eighteen or twenty-four hours at the earliest, and practically there is no danger of heart block. The immediate result of the intravenous injection is to increase the amplitude of the pulse wave. In a few minutes the frequency of the heart is slowed. Therefore, when it is desired to get speedy relief in broken compensation where the heart is rapid and the blood pressure is lower than is needed to retain the balance of the fluids in the body, when the apex and wrist are far apart, when there is great distress and restlessness, with a sense of impending disaster, strophanthin given as directed will give in most instances immediate relief which will last seventy-two hours and sometimes even longer. This relief will be accompanied by free diuresis, or will permit diuretics previously inert to become active once more. The previous use of digitalis is, however, almost a sure contraindication to the use of strophanthin. Eight deaths are on record from poisoning by the latter. In addition, the injections must not be allowed to escape into the tissues or into the wall of the vein. A high blood pressure is not necessarily a contraindication, but bradycardia always is.

New York Medical Journal, October 23, 1909.

Cancer of the Stomach.—A general consideration of the subject is given by I. E. Cantaday, who says that in more than 60 per cent of cases there must have been an antecedent condition of ulcer. The two most common types, the pyloric and the prepyloric, give initial symptoms that differ decidedly. In the former the symptoms are obstructive from the beginning, and vomiting is seen from the first. Hypertrophy and dilatation follow early. When the growth has a prepyloric location, the first signs are separately vague, but taken together are quite sufficient for a diagnosis to be made. When a cancer is implanted in the ulcer or its scar there is a slow, progressive transition, becoming more and more severe. Evidence of transition from simple ulcer to malignancy can seldom or never be found post mortem. The excision of the ulcer as a means of prophylaxis will always be of much value. Exploratory incision is advised in all cases of chronic gastric ulcer of more than recent origin. Wherever there is gastric stasis a mechanical blocking can be relieved only

by mechanical means. As a general rule, the operative mortality after gastrectomy for cancer will be from 15 to 20 per cent.

Economies of Health.—R. J. Behan discusses the statistics of modern social efforts to collate the financial loss of sickness to the community. The State can prevent this loss: (1) By prophylaxis which includes the taking of precautions against its transference from one community to another, and the State can best regulate this by registration of all cases and a better diffusion of knowledge of the omnipresence of this disease among the people and of its means of prevention and of cure. (2) By care of the tuberculous sick. The tuberculous sick should be cared for, not only through reasons of humanity, but because by their proper care and training the tendency to carelessness which is always present in every case would be markedly lessened. He lays great stress upon the duties of corporations toward their employees with reference to the adoption of life-saving devices, safety machinery, etc., and to the necessity of proper care when once a workman has been injured. He gives some interesting figures in regard to the problem as affecting the Pittsburg district.

The Thiocyanates in Solution the Natural Physiological Solvents of the Body—A Clinical Study.—B. R. LeRoy is convinced that the thiocyanates work through their molecular union with the earthy salts, thus producing a substance that is both soluble and assimilable, which the body cells readily take up and convert to their own uses, thus acquiring the power of resisting the action of certain poisons and certain microorganisms. A series of six clinical cases is epitomized. The thiocyanates are given in aqueous dilution, first making use of a 1 in 1,000 solution in distilled water: a teaspoonful of this at mealtimes and at bedtime. The percentage may be increased, but the dosage is never increased. In certain cases a 2 per cent. solution is used. As it is well known that the thiocyanates (English, sulphocyanides) are the most active poisons to both animal and vegetable life that is known, it will appear to the clinician that extreme care in administering the thiocyanates must be taken, nothing must be taken for granted, the blood pressure must be studied with care and kept in a normal limit by increasing or diminishing the dose of the chemical. It will be highly advisable to give the patient scrub baths with rub down of an acid solution, to regulate the bowels by some simple means, and to order the patient to live a simple life. The scrub baths followed by the acid wash-down are as essential as the dietary control, for in cases where the thiocyanates were indicated and given without the baths to reduce the content of ammonia chemical changes are produced which are harmful, and symptoms of disease are intensified. One must always endeavor to lessen the content of ammonia in the system before giving the thiocyanates. The reaction of a normal amount of the remedy in the saliva is indicated by a blood-red color given the saliva with an acid solution of ferric chloride.

Rectal Erosions: A New Method of Examination.—S. Lewis believes that a superficial form of anal fissure which may be called an erosion is more common than is generally supposed. They lie at the bottom of folds, and are obscured by the sphincteric contractions. He employs the glass rectal dilators, sold by dealers in sets of three. One of these, as large as patient will bear, should be lubricated with glycerin or some other transparent lubricant (not petrolatum) and inserted. The entire surface is at once open to inspection. The normal mucosa is pale from pressure; and fissures, erosions, or emboli are as clearly seen as if on an open page before you. Partial relief of pressure by tilting or partial withdrawal of the "speculum" may assist. An electric diagnostic lamp is useful. The most satisfactory treatment he has employed has been potassium permanganate crystal or saturated solution followed by powders, ointments, or suppositories, as the case may demand.

The Lancet, October 16, 1909.

The Operative Treatment of Cataract.—The article of A. E. J. Lister is a clinical study of 576 personal operations done according to the method of Major Smith of the English army medical service. Of this entire number only two eyes were lost by sepsis. The author attributes this small number to the use of a douche of mercury perchloride, one to two thousand. This solution is a strong one for the eyes, but the patients are all under cocaine anesthesia, and the author thinks that this preparation in the strength named is a potent factor, as few of his cases were given any preliminary treatment to the conjunctiva. Troublesome lacrymation occurred in a few cases, but yielded to instillation of a weak zinc sulphate solution and boric acid drops. Escape of the vitreous occurred 29 times, but this accident diminishes with the skill and experience of the operator. The author passes on to consider the technique of the operation, dwelling especially on the importance of quickness on the part of the operator. In regard to the effects of the escape of the vitreous, he says that 98 cases were examined over three years after the operation had been performed, and in no case was there any detachment of the retina. It is quite probable that the eye in operations hampered with débris and the capsule of the lens which, apart from those cases in which definite iritis occurs, must usually cause some degree of irritation, does suffer more serious damage than does the eye which is free from any irritating material. On account of having so large a wound it is possible to remove most of the débris, so that the condition in these cases is not quite the same as it is in the ordinary capsulotomy operation. We have referred to but a few of the many interesting points of the original paper.

Venous Anesthesia.—A report of several cases is given by C. M. Page and S. G. MacDonald, who followed Bier's method. The skin is prepared as usual and then a sterilized Esmarch's bandage is firmly bound round the limb as high as the upper limit of the operative area. Above this and in contact with its last turn is fastened another rubber bandage, sufficiently tight to stop the arterial circulation. The bandage covering the distal part of the limb is now removed and a third bandage is firmly wound round the limb at the lower limit of the operative area. This bandage must be tight enough to prevent diffusion of the injected fluid into the distal part of the limb. In the leg a cannula is tied into the internal saphenous vein. Small vessels are now secured to prevent leakage and a syringe capable of holding 100 c.c. is attached by a tube to the cannula. The fluid is then gradually injected, and as infiltration sets in the area swells and becomes of a dusky white color. Complete anesthesia is secured in from five to fifteen minutes. When it is secured the cannula is removed and the vein tied off. The skin incision, unless it falls into line with the operative incision, is sutured and operative measures are then proceeded with. The anesthetic agent employed by the author was cocaine novocaine, and he says the danger of toxic symptoms from it will only arise at the moment when the upper bandage is loosened or when perfect hemostasis has not been secured. In his own cases of amputation the amount of novocaine has not been sufficient to alter the pulse rate except in the case of an old man whose arteries were extremely rigid. In fat subjects this method is inferior to that of spinal anesthesia for operations on the lower limb, owing to the difficulty of finding the vein. This part of the operation does not require in the average patient more than fifteen minutes.

Thyroidectomy and a Theory of Cancer Causation.—W. Stuart-Low gives the histories of five cases, saying that after years of observation of cancer and sarcoma in all stages he has come to the conclusion, looking at the thyroid gland as the flywheel of body growth and metabolism, that this organ is very liable to overwork, that the body metabolism is liable in this manner to become overworked, and that the thyroid may thus become a causation factor in the origin and continuation of malignant disease. He therefore advises more or less complete excision of the thyroid in inoperable carcinoma as the best means of eliminating or ameliorating a disturbing factor in the diseased organism of the carcinomatous. The results of his operations seem to show that the elimination of the thyroid has an influence on these inoperable malignant growths. It seems to have a deterrent effect on the rate of growth of the primary tumor, and the secondary glands seem to be favorably affected also. In his own cases the glands were softened and less painful. In all the pain was quickly relieved, the patients began to put on weight, and there was a distinct slowing of the pulse rate.

British Medical Journal, October 16, 1909.

The Origin of the Presystolic Murmur.—A. E. Cohn refers to a patient under observation for mitral stenosis who showed constantly in his venous curve a long a-c interval. During his last failure in compensation he was brought into hospital, where digitalis was given him. After two weeks his venous curve showed incomplete heart block, 2 in 1. Auscultation at the apex showed that when the heart was beating regularly a presytolic murmur was always heard. During the periods when the ventricles were silent the murmur corresponding to the presystolic murmur persisted, and was synchronous with a certain wave in the venous curve. It was clear that auscultatory

phenomenon occurred in a cardiac cycle in which there was a silent period of the ventricle seen in the pulse curves. It seems justified to conclude that the auricle, which alone was beating, was responsible for the production of this presystolic murmur. Not only were the heart signs wanting, but the systolic and diastolic murmurs which were features in the auscultatory signs in the case were absent in the cycles noted.

Determination of Tubercle Bacilli in the Blood of Persons Suffering from Phthisis.—A. M. Hewat and H. G. Sutherland refer to the work of Rosenberger and Forsyth, and are unable to agree with them. At no stage of localized pulmonary tuberculosis was the bacillus demonstrable in the blood. They allude also to the work of Schroeder and Colton of the United States Bureau of Animal Industry, who tested the blood of 42 cattle in all stages of tuberculosis by intraabdominal injections into guinea pigs with negative results in every case. In only 1 out of 20 cases was it possible for Hewat and Sutherland to demonstrate tubercle bacilli in the blood. In this case two acid-fast bacilli were found, morphologically resembling the tubercle bacillus. A second examination of the blood of the same patient proved negative after a prolonged search, so that they were led to believe that the presence of the two bacilli referred to was accidental.

Dystocia Due to Uterine Ventrofixation.—W. Smith reports a fatal case, the patient's operation being done five years before. Pains began September 13, but did no good. She was kept with suitable doses of opium and chloral. In the neck the os was somewhat dilated and the membranes protruded in a sausage-like bag. Next day they ruptured. Twelve hours later forceps were tried, but it was impossible to get the second blade on. Version was then tried, but found impossible, and perforation could not be done. Cesarean section was then done by the surgeon, who had done the ventrofixation five years before. The tubes were tied and cut. The uterine wall was edematous and the cavity stained with meconium. The fetus was macerated. The patient was in good condition after operation, but died of shock in forty-one hours.

Intermittent Closing of Cerebral Arteries.—W. Russell discusses the relations of this circulatory disturbance to temporary and permanent paralysis. It led to impairment or suspension of the function of the part affected, as manifested by sensory disturbances and motor faltering, or paralysis. It favors thrombosis in certain states of the vessel wall, or of the blood itself, or of both. If the heart be weak the blood flow is the more easily arrested, thrombosis is favored, and the risk of softening is the greater. If the heart be strong and the vessel not sound, hemorrhage is liable to occur. The bleeding does not occur in the closed portion of the vessel. It must take place on the proximal side, where the pressure is raised because of the distal closing. The causes of this accident are found in the gouty and rheumatic, in impaired metabolism, fatigue, toxic conditions of skin and kidneys, mental overwork, etc. Treatment should be directed toward the removal of the abnormal vessel irritability. Plethoric patients are not the greatest sufferers from this accident. Purgative and all extreme measures may be harmful. The irritable tonicity of the vessel wall is often controlled by spirits of niter. In more urgent cases ¼ to ½ gr. doses of erythrol tetranitrite may be given every three or four hours. The action is temporary, but it allows time for the bowels to act fully and for the elimination of waste products. Iodide of potassium is often serviceable. Violent purging in feeble circulation should be carefully avoided. Nux vomica is a useful tonic.

Berliner klinische Wochenschrift, October 4, 1909.

The X-Ray and Diphtheria Toxin.—Gerhartz reports a study of the effect of the *x*-ray on diphtheria toxin. His experiments were of two series. In one he took known amounts of a toxin of a known strength. From twice to six times the fatal dose for rabbits of definite size was given. In each series there were two rabbits of the same size. To one was given the toxin unaltered, and to the other a similar amount which had been exposed for a longer or shorter time to the *x*-ray. In each case the toxin which had been so treated was less toxic than the untreated. In the second series the similar doses of the toxin were given at once to rabbits, one of which was exposed to the *x*-rays. Here, too, the rays showed a definite protective influence in that these rabbits outlived the controls.

Münchener medizinische Wochenschrift, October 5, 1909.

The Antiproteolytic Substances in the Blood Serum of Healthy and Ill Infants.—F. Lust reviews the literature of the clinical significance of the estimation of antiferments in the blood, and emphasizes the fact that an increase of antiferments is found especially in cachectic conditions, as carcinoma. This increase of antiferments seems to be dependent not upon leucocytosis, but upon the amount of absolute cell destruction which is going on in the body—the proteolytic catabolism. On the grounds of these facts he investigated the antiferment content of the blood of a series of healthy and ill infants to learn whether the unexplainable atrophies of infancy were related to the adult cachexias. The method used, was Fuld and Gross' trypsin estimation method by the digestion of casein. The end reaction being estimated by the action of acetic acid upon the solution. On account of the small amount of serum obtainable, but reduced amounts of trypsin and of casein were used, and the serum was diluted 1:5 in physiological saline. A study of ten healthy children showed an antiferment content of the serum of much the same strength as in the adult. The index was from 0.2 to 0.25. That is, that 0.2-0.25 c.c. of a 0.2 per cent. solution of trypsin was required to overcome the antiferment in 0.05 c.c. serum (1:5). The age of the infant did not influence the index. Twenty-two cases of chronic indigestion, many emaciated and atrophic, were tested. Twenty-one of these gave a perfectly normal index; one only was 0.35. Nine cases of the class named by Finkelstein, "decomposition cases," were examined, infants with a steady loss of weight without gastrointestinal symptoms. These were also normal in index. This fact might be due to one of two points: either infants vary from adults in not producing antiferment from cell destruction, or these cases did not produce a true proteolysis. As others have shown that in metabolic experiments on such cases, the N-balance is practically never negative, and that the loss of weight is due to fat, not tissue destruction, the second hypothesis is correct. In acute gastrointestinal diseases conditions were different. In these there was a definite increase of antiferment from 0.35 to 0.5. The two cases with an index of 0.35 recovered; the five with higher indices died. This suggests the possibility of using the antiferment index as a prognostic aid. The theoretical importance of these findings are great in that they show that if there is a relation between the production of antiferment and proteolysis, in the chronic cases of marasmus there is no true tissue destruction, while in acute dyspepsia there is.

The Chemistry of Tuberculous Sputum.—Prorok has made quantitative estimations of the amount of albumin and albumoses in the sputum of phthisis patients. The method was as follows: A measured amount of sputum was shaken with 3 per cent. acetic acid, filtered, and the filtrate washed with the same solution. The albumin and albumoses went through to the filtrate. To this was added NaOH, until the specimen was but faintly acid, and the albumin salted out with NaCl, collected on a filter, washed with hot water, alcohol, and ether, and weighed. The filtrate and wash waters were saturated with $ZnSO_4$, to salt out the albumoses. These were collected on a filter and the N estimated by the Kjeldahl method. The method was used on twenty-one cases. The amount of albumin varied from 0.06 per cent. to 2.03 per cent., and of albumoses from 0.029 per cent. to 1.04 per cent. These results are higher than those obtained by other observers.

Deutsche medizinische Wochenschrift, September 30 *and October* 7, 1909.

Excision of Goiter and Local Anesthesia.—Hackenbruch describes in full his technique in employing local anesthesia in the operation of thyroidectomy. In spite of a certain nervous excitement, due to an appreciation of the course of the operative procedure, the markedly decreased risk with local anesthesia makes its use most desirable. The preliminary treatment is psychic and medicinal. The psychic treatment consists in assuring the patient that the operation will be entirely painless. To do this with the lower classes it is advisable to have the patient admitted to the ward some days before the operation in order that by conversation with other patients they may be reassured of this point. The medicinal preliminary treatment consists in for several days administering the tincture of strophanthus to quiet the pulse. The night before the operation from 7 to 15 grains of veronal is given. Just before the operation an opiate is administered. In the earlier cases this was morphine hypodermically, but later tinctura opii is used by mouth, 20 to 30 drops one hour before the operation, and repeated in one-half hour. The method of administration of the anesthetic used is the author's circular injection method. The entire tumor is surrounded with the anesthetic. Novocaine, 0.5 per cent.

in 0.8 per cent. salt solution, is used as an anesthetic. The solution is made fresh each time it is used, and to each 10 c.c. four drops of suprarenal extract is added. A syringe with a capacity of 10 c.c., with a needle 5 cm. long, and of the smallest possible caliber is used. The technique of the injection is as follows: First, at the outer upper pole of the goiter the needle is injected quickly through the skin, and then slowly inserted with continual injections deeply to the neighborhood of the cervical vertebra, in the direction of the great horn of the hyoid bone. It is then withdrawn until the point is just under the skin, and in a similar manner reinserted just under the skin to the middle line of the neck; a third insertion deep to the spine, and a fourth down the side of the tumor are made, all through the original skin puncture. A second puncture is made at the lower outer pole, just above the clavicle, and three injections, deep, upward, and medially are made. Repeating the procedure on the opposite side insures complete anesthesia of the entire gland, which will last for about one hour. In no case has any unfavorable symptom occurred due to the anesthetic.

The Significance of the Wassermann Reaction in Rhinolaryngology.—Weinstein reports a series of cases of disease of the nose and throat in which the Wassermann reaction was used, and from his results concludes that this reaction is a most valuable diagnostic aid. Its clinical availability is undoubted. In rhinolaryngology this aid must be accorded especial respect, as by its means many cases may be cleared up which without it would remain obscure. The positive reaction points with absolute certainty to an active syphilitic infection. A negative reaction is not absolutely definite, but gives a very strong probability (90 per cent.) of the absence of syphilis. In every doubtful case the Wassermann reaction should be used to establish the diagnosis.

The Most Important Mode of Contagion in Tuberculosis in Man.—P. v. Baumgarten says that there are three theories of the mode of transmission of the tubercle bacillus. The believers in the aerogenous theory hold that it is the only means of infection, and that family and workshop epidemics result from air contagion through dust. Experience and experiments, however, do not uphold this view. The enterogenous theory maintains that the disease is obtained by swallowing the bovine bacillus which attacks the glands. This form of infection, however, never causes a progressive tuberculosis. By the genneogenous theory the author means germination and congenital infection, the transmission of the bacillus through the germinal cells or from the mother to the fetus *in utero*. The possibility of this is proved by many conclusive experiments. It has been demonstrated also in man, at first rarely, but later more frequently, as the difficulty in discovering the organism in the fetus is being overcome by increasing knowledge and improved technique. More and more frequently we are learning to recognize this form of inborn tuberculosis. We are now beginning to appreciate the soundness of this teaching. It is not too bold to expect that the future general opinion will be that humanity should pay less attention to the individual social relation of the patients than to the prevention of the congenital implantation of the organism. In other words, v. Baumgarten says, the aerogenous and enterogenous will give way more and more to the "genneogenous" theory.

Implantation of Thyroid Gland in Myxedema and Cretinism.—V. Bramann calls attention to the former operations to implant thyroid gland into the human body in cases of myxedema. These efforts have been made into the subcutaneous tissue, peritoneum, spleen, bone marrow, and in the neighborhood of great vessels, usually with but very temporary results. He then reports three cases in which he implanted pieces of thyroid, 6 x 1 cm., into the bone marrow of the tibia with very good results. In this operation he carefully scraped out all marrow from the neighborhood of the implantation so that the thyroid came in direct contact with the bone, a fact which he believes explains his success. He says that the ideal operation is transplantations with vessel anastomosis, but until the technique of that operation is so improved as to bring its accomplishment within the range of practical possibility, one will find that the present operation is of use.

The Staining of Moist Preparations with the Azur-Eosin Method.—Giemsa reports a modification of his well-known stain by means of which moist specimens may be stained. The various steps are as follows: (1) Fix the moist, thin cover slip smear in sublimate alcohol (concentrated watery sublimate solution two parts, absolute alcohol one part), for 12 to 24 hours or longer. (Throw the glass in with the smear down on the solution; later immerse and turn over.) (2) Wash quickly in water and for from 5 to 10 minutes in a solution composed of potassium iodide 2 gm., distilled water 100 c.c., and Lugal's solution 3 c.c. (smear side up; gently oscillate). Immediately afterwards (3) wash quickly in water, and for 10 minutes in a 0.5 per cent. watery solution of sodium thiosulphate, by which method the iodine yellow preparation is completely bleached. (Smear side up, oscillating.) (4) Five minutes in running water. (5) Stain with freshly diluted Giemsa solution (1 drop to one, two or more c.c.) for one to twelve hours, or longer. After the first half hour pour off the old stain and add fresh. (6) Pour off and pass through (a) acetone 95 c.c., xylol 5 c.c., (b) acetone 70 c.c., xylol 30 c.c., (c) acetone 70 c.c., xylol 30 c.c., (d) xylol pure. (7) embed in cedar oil.

French and Italian Journals.

A New Method of Treatment of Syphilis, with Reference to Abortion of the Lesions and Attenuation of Its Virulence.—H. Hallopeau combines local treatment with general treatment in an attempt to abort, or attenuate the virus of the syphilitic infection. For local treatment he injects at the seat of the ulcer, or in the neighboring lymphatics, atoxyl or one of its derivatives, ten centigrams of each in boiled water. In this way he acts directly upon the treponemata included in the chancre, and those which have infiltered the lymphatics, or have been transported into the inguinal glands, which are very virulent. The diagnosis should be made by the use of the ultramicroscope, the quickest method of diagnosis. A local pomade of crystallized atoxyl may be applied over the initial lesion. The injections of atoxyl should be continued daily up to the period of secondary symptoms, that is, for forty-two days. This will prevent the roseola, and the adenopathies, since numerous foci of proliferation of the treponema will be sterilized. An internal treatment by mercury and iodide of potassium is put into practice at the same time, to act against the germs in the circulation. These various methods of treatment can be associated without disadvantage. The results are that the manifestations of the disease are very slight and of very short duration; there is indeed, a true abortion of secondary syphilis. The earlier this treatment is applied, Hallopeau says, the better are the results for the patient. We may hope, he thinks, to meet fewer cases of generalized syphilis, tabes, general paralysis, and cerebral syphilis in future.—*Gazette des Hopitaux*, August 3, 1909.

Vomiting of Pregnancy.—A. Pinard discusses the causation and treatment of incoercible vomiting of pregnancy. He believes it to be due to some poison manufactured in the system of the pregnant woman, which acts on the vomiting center in the medulla, as well as intoxicating the entire nervous system. It is similar to the poison that causes eclampsia. How it is manufactured, and what its cause is still unknown. One of the most serious symptoms that results from this intoxication is an acceleration of the pulse, with lowered arterial tension. As soon as this occurs, and the pulse has risen to over 100 per minute, it becomes necessary without delay to induce premature labor, else death will soon close the scene. In less severe cases an absolute milk diet may cause relief of the symptoms. The author has rarely seen a febrile condition occur until just before death. The cause of all cases of vomiting of pregnancy is the same; in some women the intoxication is overcome, vomiting ceases, and pregnancy goes on to term; in others the intoxication goes on to a fatal issue unless pregnancy is interrupted. —*Annales de Gynecologie et d'Obstetriques*, July and August, 1909.

Biological Action of Fulguration.—Ghilarducci describes several cases of malignant tumors treated by the method of fulguration. The instrument consisted of a powerful transformer with closed, magnetic circle, a special resonator, and an electrode with a current of air which permits of modification of the sparks. The immediate results have been good in torpid lesions of various nature, such as tuberculosis, and in a case of nodous lupus of the hand. Analgesia, lymphorrhea, the eschar, and the process of granulation and cicatrization of enormous losses of substance were all demonstrated. He experimented on fulguration of the spinal medulla and peripheral nerves in a rabbit. Some of these experiments showed that the spark had an almost selective action on nerve elements. Ghilarducci offers the suggestion that the analgesic action of fulguration may lead to experimentation on nerves exposed in cases of inveterate neuralgia.—*La Riforma Medica*, September, 1909.

Book Reviews.

Electricity in Gynecology. The Practical Use of Electricity in Diseases of Women. By May Cushman Rice, M.D.; Professor of Gynecology and Clinician in the Illinois School of Electro-Therapeutics; Member of the Chicago Medical Society and American Medical Association. Illustrated. Chicago: L. I. Laing & Co., 1909.

This is a small volume of 150 pages, dealing with electricity in gynecology. It is intended to supplement a course in electrotherapy. As an introductory work it can be commended. The author is quite conservative, and does not claim that electricity will cure everything, nor does she urge its use when other means are considered preferable.

Lehrbuch der Magenkrankheiten. Für Aerzte und Studierende. Von Dr. Hans Elsner, Specialarzt für Magen- und Darmkrankheiten in Berlin. Mit 46 Abbildungen. Berlin: Verlag von S. Karger, 1909.

Elsner has attempted to write a book on the diseases of the stomach that should rank midway between the numerous short treatises on the subject used by students and the equally numerous exhaustive monographs appealing to specialists in this branch of medicine. His volume is intended for the general practitioner; it contains all that is new in our knowledge of gastric disorders, without going into interminable discussions of the theories and explanations of them. The author first considers the general principles of diagnosis in the diseases of the stomach, giving a plan for obtaining the patient's story of his complaint and naming the diagnostic data to be obtained by inspection, palpation, and the mechanical methods of examination. Under the latter heading the use of the stomach tube, the inflation of the organ, Röntgenological examination, gastrodiaphany and gastroscopy are fully considered. Abundant space is given to the chemical examination of stomach contents and to the demonstration of occult blood in the feces, the search for which is considered by the author to form perhaps the most important single procedure in the diagnosis of stomach affections. Elsner very properly warns against the numerous errors into which the inexperienced physician may fall in interpreting the findings—the changes in the chemistry of the gastric juice caused by nervous influences and by the effect of the menstrual period in women, the simulation of spontaneous bleeding occasioned by trauma caused by the stomach tube, the appearance of occult blood explained by the presence of meat in the diet, or such sources of bleeding as hemorrhoids, nasal polypi, hypertrophied adenoid tissues, etc. The guaiac test for blood is the one that seems to be most favored by the author.

The second part of the book is devoted to the symptomatology, diagnosis, and treatment of the special affections of the stomach, whether of functional or of organic origin. The various chapters contain a well-digested presentation of the latest knowledge of the disturbances of chemical secretion in the stomach, such as achylia, hyperchlorhydria, hypersecretion, gastrosuccorrhea, etc.; such organic lesions as gastric ulcer and carcinoma of the stomach, and changes in size and shape of the organ depending on them are next considered. In the diagnosis of carcinoma, Elsner lays stress upon the use of bismuth suspensions for Röntgenological work; in the treatment of ulcer he gives a fair presentation of the milk diet of Leube and the high protein diet of Lenhartz. Personally, Elsner inclines toward the latter treatment, though he insists upon the necessity of selecting the nature of treatment to suit individual conditions, and not a theoretical picture of the affection.

The book thus forms a very useful compilation for students of medicine and for physicians. It aims to point out the rational and the logical that ought to replace the cut-and-dried diagnostic and therapeutic methods of the past in this difficult branch of medical activity. We heartily recommend the volume to the attention of the American medical public.

History of Yellow Fever. By George Augustin. New Orleans: Published by the author, 1909.

This book of 1200 pages, while necessarily a compilation, represents a vast amount of research work extending over more than a decade. The author, while not a medical man, has had exceptional opportunities for the conduction of the work, being Assistant Secretary of the Louisiana State Medical Society; Assistant Librarian of the New Orleans Medical Society; Special Stenographer for the Marine Hospital physicians, combating the yellow fever outbreak in New Orleans in 1897, etc. In the medical aspects of his subject the author has been assisted by a considerable number of physicians of local and national reputation as authorities on yellow fever, and their special articles on the cause, pathology, prevention, diagnosis, prognosis, and treatment of this disease represent the very latest knowledge along their respective lines of contribution. The book takes up, in Part I, a brief historical summary of the ravages of pestilential disease, the great epidemics of the middle ages, and the relation of insects to the propagation of disease. Part II discusses pertinent points about yellow fever, its nomenclature and a historical summary as to its probable place of origin. In Part III, the author gives the history of yellow fever by localities, including outbreaks and epidemics occurring in various regions and countries of Asia, Africa, Europe, and the three Americas. The chronology of all these outbreaks is given, and the literature and reports of the time are largely quoted for illustrative purposes. Part IV discusses various phases of the yellow fever outbreak in New Orleans in 1905, while Part V treats of the purely medical aspects of the disease as already referred to. The book cannot fail to be of great value, not only to the sanitarian and student of epidemiology, but also to the practising physician, especially to such of the latter as are located within the habitat of the yellow fever mosquito. The book is more or less modeled along the lines of the magnificent "History of Asiatic Cholera," by the late Dr. E. O. Shakespeare of Philadelphia, of which work Mr. Augustin's book will prove itself a worthy companion.

Short Talks with Young Mothers on the Management of Infants and Young Children. By Charles Gilmore Kerley, M.D., Professor of Diseases of Children, New York Polyclinic Medical School and Hospital; Attending Physician to the New York Infant Asylum; Assistant Attending Physician to the Babies' Hospital, New York; Consulting Physician New York Home for Crippled and Destitute Children; Consulting Pediatrist, Greenwich Hospital; Consulting Physician, Savilla Home, N. Y. Second edition. Revised and enlarged. New York and London: G. P. Putnam's Sons, 1909.

This little book, now appearing in its second edition, is intended to cover the multiplicity of details which modern scientific pediatrics requires that the young mother should know in order to give her babe the best chance to grow to healthy manhood. All the minutiæ of nursing, feeding, and care are described. The latter half of the book gives brief epitomes of the etiology, symptomatology, and treatment of the commoner diseases of childhood. A chapter is also devoted to the delicate child. As a collection of facts of value to the mother this book is certainly adequate.

A Text-Book of Practical Therapeutics. With especial reference to the application of remedial measures to disease and their employment upon a rational basis. By Hobart Amory Hare, M.D., Professor of Therapeutics in the Jefferson Medical College of Philadelphia. Thirteenth edition, thoroughly revised. Octavo, 951 pages, with 122 engravings, and 4 full-page colored plates. Philadelphia and New York: Lea & Febiger, 1909.

Few books are so well known or so popular with the American medical public as Hare's Therapeutics. Little need, therefore, be said about the new thirteenth edition of the book except to welcome its appearance and to notice the newer matter considered in its pages. Dr. Hare has, as usual, subjected his book to a thorough revision, giving the reader the benefit of his wide reading and experience in the use of the newest remedial measures, whether pharmacological or physical. Among the recently introduced remedies we note that salicylate of ethyl in the systemic treatment of rheumatic affections is given sufficient notice; the use of magnesium sulphate locally as an analgesic and of picric acid in the treatment of burns is discussed; Lenhart's treatment in gastric ulcer; Murphy's treatment of septic peritonitis; the newer antitoxins for gonorrheal infection and for cerebrospinal meningitis, and the more recent local and general anesthetics are included in the additions to the book. In a word, Dr. Hare's work is a compendium of all the recent as well as the old and proven methods and measures in the treatment of disease, and in addition is a treatise on the action and properties of drugs. It brings the study of drugs in relation to the practice of medicine and in its hopeful and well-balanced presentation of the rôle of medicines in the therapy of disease it serves as a wholesome set-off to the more fashionable therapeutic nihilism of the day. The book is perfectly annoted and cross-indexed, so that it serves as a quick book of reference in any emergency. It can be recommended to students as a text-book and to practitioners as a daily guide in the best practice of the day in the treatment of disease.

Society Reports.

AMERICAN ROENTGEN RAY SOCIETY.

Tenth Annual Meeting, Held in Atlantic City, September 23, 24, and 25, 1909.

THE PRESIDENT, DR. GEORGE C. JOHNSTON OF PITTSBURG, PA., IN THE CHAIR.

Officers.—The following officers were elected for the ensuing year: *President,* Dr. Geo. E. Pfahler of Philadelphia; *Vice-Presidents,* Drs. Vernon J. Willey of Rochester, Minn.; C. E. Coon of Syracuse, N. Y.; R. D. Connell of St. Louis, Mo.; and R. D. Hammond of Providence, R. I.; *Secretary,* Dr. Percy Brown of Boston; *Treasurer,* Dr. Charles F. Bowen of Columbus, Ohio.

Detroit was selected for the next place of meeting, the time to be decided on later by the executive committee.

It was voted to discontinue the publication of the transactions in the form of an annual volume, and to substitute therefor an official journal, to be published quarterly, and to be devoted entirely to the use of the Roentgen ray in medicine. Dr. P. M. Hickey of Detroit was elected editor. The first issue of the journal will appear about December 1.

Roentgen Ray Examination of the Mastoid Region.—Dr. SIDNEY LANGE of Cincinnati emphasized the value of skiagraphic examination of the mastoid region in the diagnosis of diseased conditions of the mastoid. The radiograms were made with the patient lying on his side, the mastoid resting against the plate and the rays directed from above and behind, entering obliquely just below the parietal eminence of the upper side and pointing toward the mastoid of the opposite side. The axis of the compression cylinder was tilted upward (cephalad) at an angle of 25 degrees, from Reid's base line, and inclining backward 20 degrees from a plane passing vertically through both external auditory meati. The external ear should be folded forward, because its cartilages sometimes cast faint shadows on the plate. The exposure was of from five to ten seconds' duration. Both sides must be skiagraphed for purposes of comparison. The same tube might be used for both exposures to insure equality of definition and penetration. It was desirous to obtain as great uniformity in the two plates as was possible. The comparison of the two sides was facilitated by taking both on an 11 x 14 plate, covering over half the plate with lead while exposing the other half. A small compression cylinder, 4 or 4½ inches in diameter, would improve the quality of the plates.

The Relations Between Bodily Deformity and Gastrointestinal Irregularities.—Dr. PERCY BROWN of Boston called attention to two classes of cases, the first a class in which an apparent postural deformity absorbed attention to the exclusion of many subjective signs, and the second class one in which gastrointestinal symptoms persisted because of failure to recognize the real cause of the trouble. The Roentgen method of diagnosis was applicable in each class, binding into associated correlation the clinical aspects of bodily disfigurement or deformity and those of various ill-conditioned alimentary functions. The etiological complex in these abnormal conditions of the alimentary tract the author divided into (1) accidental deformities and (2) wilful disfigurements of the body. He found that in cases of lateral spinal curvatures the stomach might be so outlined as to make it appear almost inconceivable that ordinary peristalsis was not interfered with seriously. It had often appeared as if the stomach were twisted on its vertical axis. In kyphotic asymmetries of the spine, especially of tuberculous origin, Brown found no appearance in the shape and position of the stomach differing from those in scoliotic cases. It seemed, therefore, as if the torsion commonly observed in the scoliotic cases had a certain bearing on the malposition of the stomach, though not to such an extent as on the heart and lungs. Another large subgroup of cases in which alimentary imperfections were often found were those in which occupation postures and other postural habits were the underlying roots of the evil, but in which the perversion had not become structural. In this class were the milder types of postural lateral spinal curvature, round back, stoop shoulder, and the like. The wilful disfigurements of the body leading to visceral ptosis were the result of tight lacing, and so forth. In one case seen by Dr. Brown there was a most marked ptosis of the transverse colon, and he was of the opinion that improper shoeing had largely to do with disinclination to walk, followed by general lazy habits of inertia and overeating.

Dr. CHARLES M. HAZEN of Richmond, Va., pointed out that in most of these cases there was a lack of tone in the spinal column, which probably had been overlooked as a cause of condition.

X-Ray Diagnosis of Achondroplasia and Cretinism.—Dr. HENRY K. PANCOAST of Philadelphia, Pa., stated that whereas cretinism did not present any distinctly characteristic radiographic features, it was not likely to be mistaken for any other condition, such as achondroplasia or rickets. On the other hand, achondroplasia presented very striking characteristic radiographic features. There was a very decided deficiency in the epiphyseal development of the shafts or diaphyses of the extremities, making them appear not only very short actually, but also relatively, in comparison with other long bones, such as the ribs and clavicle. They also appeared too thick for their length. There was an abrupt expansion of the diaphyses or shafts in the neighborhood of the diaphysoepiphyseal junction, a rather abrupt bowing of the lower end of the femur, and the upper end of the tibia, with a fairly well developed head of the femur, poorly developed, short, thin neck, and a far better relative development of the trochanter, the latter being manifest in the adjacent portions of the shaft even before ossification in the epiphyses had begun, especially in the lesser trochanter. The appearance of the hands and feet was also characteristic, as was the appearance of the structure of cancellous bone. There was a tendency to symmetrical osteomatous growths on the long bones of the upper extremities, a deficient and irregular ossification and growth at the epiphyseal ends of the diaphyses, particularly in the knee.

Dr. CHARLES LESTER LEONARD of Philadelphia examined a case of cretinism about eight years ago, in which he found separate foci of ossification in the ends of the tibia and femur. There appeared to be three rings of ossification in all the small bones of the feet. He suggested that this might be a point of differentiation.

Dr. P. M. HICKEY of Detroit found in these cases a corresponding development or lack of development in the bones and in the mental capacity of the patient, the one keeping pace with the other.

Stereoscopic Roentgenography of the Chest.—Dr. P. M. HICKEY of Detroit urged making use of the stereoscopic method of roentgenography in the study of the pathology of the osseous system on all possible occasions. In the elucidation of fractures and dislocations it was far superior to plates which were made in two directions. By making two plates of the patient's chest during one respiratory pause all the difficulty heretofore encountered in this work would be obviated. To further this end, he had designed an apparatus which moved the tube rapidly, and which permitted of rapid changing of the plate. The tube holder consisted of a firm upright mounted on rollers and carrying a heavy board faced with lead, which could be adjusted at any height by means of a counterweight. The two supports which carried the tube were adjusted to

a smaller piece of lead covered board, which slid in two grooves. This board was provided with antifriction rolls. The plate holder consisted of an oblong frame, supported on two uprights. This frame could also be adjusted for height. Within the oblong frame was a plate carrier which held two 11 x 14 plates. This plate carrier was also provided with antifriction rollers, so that the slightest touch was sufficient to change the plate rapidly. The patient was instructed to hold his breath, one exposure was made, and as soon as the light vanished in the tube the assistant pulled the two strings, one of which moved the tube and the other the plate holder. The second exposure was then made. The time which elapsed between the two exposures was less than two seconds. To produce the stereoscopic effect the mirror stereoscope was used.

Roentgen Diagnosis of Pulmonary Lesions.—Dr. Charles Lester Leonard of Philadelphia stated that the Roentgen method of examination of the chest was of great value in adding to the knowledge obtained by other methods of physical diagnosis. This was particularly true in the case of earlier tuberculous lesions, especially the deep-seated, peribronchial infiltrations, and bronchial adenitis. In more advanced cases it added an element of greater accuracy and detail in localizing the affected areas, and corroborated the physical signs, while in all cases it was a mechanical method of registering observations which could be compared with others at a later date. The study of evident areas of consolidation, softening, and cavitation determined more acurately the situation and extent, while not infrequently deeply situated areas of consolidation and cavities had been shown on the skiagraph that had escaped detection by other methods. The increase in density produced by thickened pleura could not be differentiated from an equal area of infiltration except by a stereoroentgenogram. The results of a pleurisy, such as a localized empyema, or a pyo- and hydropneumothorax, could be distinctly shown. Besides the alterations in the lungs and pleura produced by tuberculosis, the Roentgen rays disclosed pericardial effusions and thickenings of tuberculous origin. Other features seen in the skiagram were the relative height of the diaphragm on both sides, the relations of the heart and larger blood-vessels, calcification of the costosternal cartilages, frequently noted in over seventy cases studied by the author. Attention was directed to the frequency of occurrence of such a calcification in tuberculous cases.

Dr. P. M. Hickey of Detroit sounded a note of warning with reference to interpreting shadows around the root of the lung as being due to enlarged glands, when in reality they were the result of a chronic inflammation around the bronchi. In two cases a diagnosis of tuberculosis was made, but the tuberculin test failed to confirm such a diagnosis.

Dr. L. G. Cole of New York emphasized what Dr. Hickey had said, and pointed out that an extensive experience had convinced him of the superiority of the Roentgen ray as a means of diagnosing early incipient cases of tuberculosis. In the radiogram the pathological changes were apparent long before they could be detected by physical examination. The mottled appearance of the lungs was absolutely characteristic of tuberculous infiltration, whether it was around the root of the lung or at the apex.

Dr. Kennon Dunham of Cincinnati emphasized the value of the Roentgen ray in the diagnosis of pulmonary conditions, especially as an adjunct to the tuberculin test. He warned against mistaking every case of enlargement of the bronchial glands for tuberculosis, because children have enlarged glands as the result of comparatively trivial causes.

Dr. Arthur Holding of Albany pointed out that the important feature of roentgenography of the chest was not so much the making of a diagnosis as it was to ascertain the pathology present in a particular chest. In the interpretation of the negative the two sides of the chest must be compared carefully, the presence of enlarged glands weighed cautiously, and the difference in the doming of the diaphragm noted.

Dr. George C. Johnston of Pittsburg mentioned that not infrequently a few small doses of potassium iodide, about three grains three times a day, would enable one to make a correct interpretation of a skiagram. It produced a localized congestion which materially facilitated the diagnosis of tuberculosis. He also stated that syphilis of the lung might be mistaken for tuberculosis, and cautioned against such an error.

Dr. Dunham stated that a dose of tuberculin had the same effect in these cases as has the potassium iodide.

Roentgen Ray Diagnosis of Diseases of Bones.—Dr. W. H. Dieffenbach of New York discussed the various diseases of bone with reference to their diagnosis by means of the Roentgen ray, and exhibited skiagraphs of cases of enchondroma, osteitis, osteomyelitis, osteomalacia, fragilitas ossium, bone cysts, osteoma, arthritis deformans, osteosarcoma, syphilis of bone, tuberculosis, and gonorrheal bone lesions. The author had made a special study of the latter condition, and claimed that certain characteristic lesions were found in bone, such as (1) deformity and enlargement of joints, (2) diminution of shadow involving the peripheral portion of all bones of the affected joints, and (3) small sclerosed intraosseous areas, either in the bone shaft or epiphyses—the so-called Carleton's spots.

Dr. Percy Brown of Boston did not agree with the author that the bone changes found by him in gonorrhea were pathognomonic, because they were found in nearly every case of infectious disease.

Dr. F. H. Baetjer of Baltimore had found as the result of rather extensive experience that in gonorrhea it was only after the cartilage had been eroded that the end of the bone was attacked. The disease never attacked the shaft itself.

Technique in Calculus Diagnosis.—Dr. A. L. Gray of Richmond, Va., was convinced that in the diagnosis of urinary calculi by means of the Roentgen ray it was better to employ a cone or cylinder, because, in the first place, it obviated a source of error that might present itself in foci of calcification in the lower costal cartilages, and, second, it was an easy method of directing the rays through the kidneys to the plate by the proper adjustment of the axis of the cone; third, the compression tended to force the back into closer contact with the plate, thereby increasing the sharpness of the calculus shadow and giving a picture of small concretions that would not otherwise appear, which was especially valuable in cases of so-called "sway back." In cases of "sharp backbone" the patient might be turned slightly to one side, and, although the rays passed through the body obliquely, the distortion produced was not sufficient to interfere with a correct reading. The author favored making four plates, one of each kidney, one embracing the ureters well into the true pelvis, and the fourth of the true pelvis, including the entire surface of the symphysis pubis. To make the kidney and ureter plates the patient should be in the dorsal position, with the head low and the thighs well flexed on the pelvis; the semisitting posture with the legs outstretched was best in making the plate of the pelvis. The author also cautioned against soiling the plate by sweat, because a sweat stain could not be differentiated from a calculus shadow. He protected his plate by means of rubber dam or thin celluloid.

In the discussion by various members, it was brought out that in calculus work the compression blends should always be used and that more than one plate should be made, including the pelvis. The means adopted for getting

the back as flat and straight as possible varied. Some radiographers used inflated rubber bags, others sandbags, but all agreed in the principles involved in these procedures.

Dr. Sidney Lange demonstrated the presence of a floating kidney by placing the patient on an inclined plane, head up, and then making a second exposure with the patient in the reverse position, feet up.

Speed Mania in Radiography.—Dr. L. G. Cole of New York said that the disadvantage of making extremely rapid exposures was that thereby many good tubes were rendered useless, although it was well recognized that absolute absence of motion was essential to good detail; in chest and abdominal work the time should not exceed the time a patient could hold the breath. The author compared radiographs made in extremely short time with the transformer with those made by longer exposure, both with the transformer and coil, and eliminating the question of voluntary motion. The results were eminently more satisfactory where the apparatus and tube were not pushed to the extreme limit. He suggested, therefore, that detail, and not speed, be the object sought after in radiography.

Dr. P. M. Hickey of Detroit pointed out that speed was not always necessary, but insisted on making a skiagram as rapidly as possible, when speed was indicated. The smashing of tubes he considered a minor detail, one which must be met by encouraging the manufacturers to make better tubes. The tubes of to-day were far better than those used five years ago. Therefore, a continued improvement in the quality of tubes might be expected.

Dr. George E. Pfahler of Philadelphia pointed out that in order to photograph the moving parts of the body it must be done in a period of time that was too short for that part to move in. Of course, if detail were not essential there was no necessity for speed, but in nearly every case detail was the one thing that must be obtained in diagnostic work.

Dr. E. W. Caldwell of New York thought that when a satisfactory appliance to produce a satisfactory current for the proper excitation of tubes was produced, the speed problem would to a large extent disappear, and with it many of the difficulties of the tube manufacturer. An apparatus which would supply a tube with one hundred milliamperes would do away with high speed.

X-Ray Work in Hospitals.—Dr. Rollin H. Stevens of Detroit had made a very careful investigation of the nature and cost of the Roentgen work done in various hospitals. The total cost of the equipment in fifty-eight hospitals was $68,350, or an average per hospital of $1,102.65. The majority of the hospitals owned their own equipment; in the others the staff or the roentgenographer owned the equipment. A few of the hospitals paid the roentgenographer a salary, others divided the fees, and others paid a salary and a percentage. In most of the hospitals considerable use was made of the Roentgen ray, not only in treatment, but for diagnosis, and many of them kept very careful records, some employing a large staff of assistants in the Roentgen ray laboratory. This study showed that no hospital aiming to do scientific work could afford to be without a complete roentgenologic equipment. The expenses should be paid by the hospital, and the roentgenographer should be paid a salary proportionate to the amount of time spend in the institution. Sufficient assistants and facilities should be provided for keeping careful and accurate records, so that the Roentgen laboratory would prove a boon and not a curse.

Some Laboratory Helps.—Dr. D. R. Bowen of Rome, N. Y., described an orthodiascope made from a half-inch iron pipe which he had devised and had used with much satisfaction. One length of pipe was suspended from a hinge in the ceiling and reached to within about two feet from the floor. Attached to this rod was a sliding sleeve carrying a pivot on which another rod rotated in a vertical plane. At one end of this second rod was the weight; at the other were the adjustable forks carrying the tube and screen. He also exhibited an all metal plate holder made of brass, with the exception of the window, which was made of gauge 33 hard roller aluminum. He had found this plate holder of use in stereoscopic work.

Use of the Roentgen Ray in Goiter.—Dr. Carl Beck of New York had employed the ray in the treatment of all forms of goiter with varying success. In cases of exophthalmic goiter he favored the combination method, that is, removal of a portion of the gland followed by Roentgen irradiation. In advanced cases, where immediate operation interference was contraindicated, Roentgen treatment should be employed until the condition of the patient was more favorable to operation. He had employed the combination treatment in fourteen cases, a cure resulting in thirteen.

Tuberculous Cervical Glands.—Dr. Kennon Dunham of Cincinnati had studied 13 cases, all of which showed an enlargement of the mediastinal glands, proving conclusively, in his opinion, that it was fallacious to attempt the radical removal of the glands in the neck in the hope of eradicating the disease. He advocated the combined use of mercurial injections and Roentgen irradiation of the glands involved, at the same time giving careful attention to hygiene and diet. Surgery should be reserved for those cases where the glands were broken down and sinuses were present.

Roentgen Ray Dermatitis.—Dr. M. K. Kassabian of Philadelphia divided this form of dermatitis into (1) the acute or accidental dermatitis of the patient, and (2) the chronic dermatitis of the operator. The former, he said, occurred but rarely now because of improved apparatus and technique, although some few patients possessed an idiosyncrasy in that direction. The chronic or operators' dermatitis was contracted but rarely nowadays, although when the ray first came into use ninety per cent. of its users were affected with dermatitis sooner or later. Only the most thorough protection against exposure to the ray insured safety. The author supervised the working of his apparatus from another room by means of mirrors, and never used a fluroscope. A lead line partition separated the rooms. The dermatitis usually came on slowly, and there followed in rapid succession redness, dryness, itching, ulceration, and pain, the severity of the symptoms varying in the individual cases. In the acute dermatitis the most effectual treatment was hot normal salt solution, which was soothing and healing. In the treatment of a chronic dermatitis the essential points were to avoid exposure to the ray, avoid injury, anoint the affected parts with lanoline, touch up fissures with an organic silver solution, keep the hands warm, wear gloves, do not use soap, and immerse frequently in hot water. A posterior digital splint might be applied to promote healing of fissures, but rest, absolute rest, was a most essential factor in the treatment. Warty growths must be excised and a skin graft done. It was the only certain and satisfactory procedure.

Treatment of Tuberculous Glands with the X-Ray.—Dr. Arthur Holding of Albany, N. Y., was convinced that the Roentgen ray possessed curative powers, almost specific in character, in cases of tuberculous adenitis. This belief was based on actual experience. When the lesions were small, he used the high frequency vacuum electrode first; in the more advanced cases he resorted to the Roentgen ray at once. If the glands were small they gradually disappeared; if they were large, they broke down. He opened such glands, allowing their contents to escape, and then proceeded with the ray treatment.

Roentgen Ray in Carcinoma of the Uterus.—Dr. H. W. Dachtler of Toledo, Ohio, reported several cases to

illustrate the status of the Roentgen ray in the treatment of this condition. A special speculum, large diameter and short length, was used, and a tube of small diameter, not over six inches, in order to bring the rays as close to the seat of trouble as possible. The knee-chest position was found the most useful. Treatment was begun the second day after operation and was continued daily while the patient was in the hospital. In the advanced cases both deep and superficial irradiations were given in order to prevent a recurrence. Not sufficient time had elapsed to draw conclusions on the effectiveness of this treatment, but thus far the results had been promising.

Measurement of the X-Ray.—Dr. C. M. Peabody of South Orange, N. J., presented a preliminary report on work he had done looking toward the measurement of the Roentgen ray. The fundamental principles involved were based on known physical laws, such as "the work done by any force varies with the time through which it acts." By making a series of exposures so as to obtain plates of graduated density, various units of work were obtained, and it would be seen that the *x*-light followed the law "that the work done by a given light varies inversely as the square of the distance from the source of light." The next principle involved was that the work done by any *x*-light varied with the quantity of current passing in the tube, other conditions remaining constant. He had elaborated a slide rule graduated in terms of the equation, and it had proved a simple and efficient exposure meter, using any tube with any current and at any distance. This formula was: $\frac{D^2\ T^2}{C\ P^2} = X$. D = distance in inches between the target and plate; T = thickness of tissues in inches, making allowance for cavities; C = the current, measured in milliamperes; P = Wehnelt penetrometer reading; X = exposure time, in seconds. This formula was based on a hypothetical unit light and applied to the Lumière plate. The author believed that he was on the road to working out a positive means of measurement and promised a further report at a later date.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON PEDIATRICS.

Stated Meeting, Held May 13, 1909.

Dr. Eli Long in the Chair.

Treatment of Club Foot in an Infant.—Dr. Henry Frauenthal presented a child having a club foot put up in plaster for the purpose of bringing out a discussion as to the proper time to treat club foot in children. The consensus of opinion on this subject was that the child should wait until it was about five years of age. This baby was but three months of age, and the feet had been put up twice. The child had been under treatment for four weeks. If it had been allowed to wait until it reached the age of five years a very considerable operation would be required.

Dr. Eli Long said that the child was very young to have its feet put up in plaster, and inquired if Dr. Frauenthal knew of any one who had obtained good results from such treatment.

Dr. Frauenthal replied that he knew of ten or fifteen cases that had been treated in this way, and inside of three months the children had perfectly good feet. At an early age the deformity was easily corrected. The treatment was in opposition to the opinion of good men, but they did not get good results so quickly and easily.

A Case of Congenital Stridor.—Dr. Charles Herrman presented this case from Dr. LaFetra's service at the Vanderbilt Clinic. The labor was normal and the child apparently normal until it was two days old, when this peculiar crowing sound was heard, which had since become accentuated. The child made no noise when asleep, but when it became excited and took a deep inspiration the sound was very distinct; this was true also at times when it was nursing. The examination showed only a distinct dullness over the upper part of the sternum, which might indicate an enlarged thymus. There were two theories regarding the etiology of this condition. The one generally accepted was that it was due to a congenital malformation of the larynx; the larynx was a little different from the larynx in the adult, and as the child grew older the epiglottis unfolded and the peculiar stridor appeared. Thomson believed that there was another factor, *i.e.* an incoordination of the respiratory muscles. He did not think that the malformation was not present, but that the incoordination was the prime factor. The sound was not heard in expiration. There was no marked interference with respiration, and no other sign of obstruction. The second view was that the condition was due to an enlarged thymus, which caused this stridor by pressure. There was a lack of evidence to uphold this view. Autopsies had been performed in a number of these cases, and they always showed this peculiar form of larynx, which seemed to indicate that the form of the larynx was the cause of the trouble. The condition disappeared at the end of a year and a half. Medication had little effect upon the condition, which simply persisted for a length of time and then disappeared. Pictures were shown, illustrating the condition of the larynx in two cases of congenital stridor, and also the peculiar form of the larynx in the newborn infant as compared with the adult larynx.

A Case of Persistent Jaundice.—Dr. Herrman presented an infant four months old, also from Dr. LaFetra's service at the Vanderbilt Clinic. The parents were healthy; there was no suspicion of specific disease. There were ten other healthy children. The labor had been normal and the child was breast-fed. On the twelfth day the mother noticed that the child was jaundiced. The child had three or four large white stools daily and no vomiting. The urine contained bile pigment. The liver extended four centimeters below the border of the ribs in the mamillary line, the spleen two centimeters. The temperature was 99.6°. At the end of a month the condition and weight of the patient remained about the same. A persistent icterus neonatorum could easily be ruled out. The absence of fever was against sepsis, as were also the comparatively good general condition after a month's illness, and the presence of bile pigment in the urine. With a complete obliteration of the bile ducts the patient would have become progressively worse, and would not have shown the intermittent periods in which a small amount of bile reached the intestine. The same might be said against a new growth pressing from without. Simple catarrhal jaundice was exceedingly rare at this age, but the case probably belonged to this group. The obstructive jaundice was probably caused by a catarrhal inflammation of the bile duct of infectious origin.

A Case of Status Lymphaticus.—Dr. G. R. Satterlee presented this case. The patient was a boy, two years of age, admitted to the Washington Heights Hospital April 10, 1909. His history revealed nothing unusual except that he had had diphtheria. The child had recently had convulsions on several occasions during the night. These convulsions were becoming more frequent, and were usually ushered in by an attack of crying with apparent pain in the lower jaw. Physical examination revealed nothing abnormal except an area of distinct dullness 2 cm. to the left of the left edge of the sternum in the first and second interspaces, and extending on the right almost to the right border of the sternum, above to the upper edge of the manubrium sterni. The area of dullness was continuous below with that of cardiac dullness. This dullness was

judged to be caused by an enlarged thymus gland, as was confirmed, it seemed to him, by the *x*-ray plates. The heart was hypertrophied, the right borders being at the right edge of the sternum, the left being about one-half inch to the left of the normal. There was a systolic murmur over the base in the neighborhood of the pulmonic area. This murmur had since disappeared. The abdominal muscles were rigid, and the area of the spleen percussed dull to a moderate extent. The organ, however, could not be palpated. There were evidences of rickets, and the right testicle was undescended. There were a few adenoids and the tonsils were slightly enlarged. The deep cervical lymph nodes were palpable, and the superficial posterior cervical, axillary, epitrochlear, and inguinal nodes were enlarged. The thyroid gland was slightly enlarged and the superficial veins running down in the region of the thymus were distended as well as those in the anterior part of the thorax. Blood examination showed 4,000,000 red blood cells, slight polychromatophilia, moderate number of normoblasts, a few microblasts and 94 per cent. of hemoglobin, index L2—leucocytes, 11,000; differential count 67 per cent. polynuclear neutrophiles, 23 per cent. lymphocytes, 8 per cent. large mononuclears and transitional leucocytes, 1 per cent. eosinophile leococytes, and 1 per cent. basophile leucocytes. Examination of the feces showed them to be soft, slimy, stringy, lemon yellow, with very foul odor and much mucus microscopically. The temperature was normal during the first seven days in the hospital. The child remained in the hospital for a week, during which time he had numerous convulsions. The treatment consisted of a milk diet with milk of magnesia, and high saline colon irrigations given twice daily. The patient was taken from the hospital on April 17 and returned on April 30. The convulsions were of shorter duration, the stridor was less marked, the color of the skin had improved, and the child was somewhat brighter. Cyanosis was present during the convulsions and crying attacks lasted steadily over an hour. On May 5 an *x*-ray photograph was taken under light chloroform anesthesia. After beginning the chloroform the pulse became very irregular and intermittent, but there were no symptoms of cardiac insufficiency. A diagnosis of status lymphaticus was made based on the enlarged thymus, the dyspnea with inspiratory stridor, the enlarged veins of the neck and thorax, the convulsions, preceded by a crying fit and accompanied by inspiratory stridor. Though rickets and intestinal disturbance were present they did not seem to be the controlling factors.

Dr. Satterlee, in discussing the *x*-ray pictures of this case of status lymphaticus, said that Dr. Walton thought there was mechanical pressure due to the thymus, but he thought it was a symptom complex. Chloroforming a child in this condition seemed rather a peculiar thing to do in order to get the picture, and when they finished he had a pretty hard time with the child for a while.

Dr. Northrup asked whether there was any difference in the respiratory murmur and dullness on the two sides.

Dr. Satterlee replied that there was some dullness noted at the left; no respiratory murmur could be detected.

Dr. J. Finlay Bell of Englewood recalled the case of a child that had been admitted to the Englewood hospital a few weeks ago with pneumonia and developed inspiratory stridor and mediastinal dullness. He thought that he felt the thymus. After several weeks swelling was noted between the scapulæ. This swelling was found to contain pus from which, upon bacteriological examination, were isolated pneumococci and no other organism. This was evidently an encysted mediastinal empyema, or a mediastinal abscess which gave many of the symptoms and physical signs of status lymphaticus.

Dr. Long said that the case reminded him of one he had seen where very similar conditions were presented. There were convulsions. In this case the diagnosis was intestinal disturbance.

Dr. W. P. Northrup said that he did not often make a diagnosis of enlarged bronchical lymph nodes, but cited a case in which the child was quite well nourished and showed a distinct shadow in that region according to the *x*-ray picture. There was a decided diminution of respiration on one side, and a distinct asthma on provocation. A couple of glands above the clavicle on the same side and a distinct widening of the shadow in the region of the thymus showed as distinctly as the spinal column. On the same side there was diminished respiration, bronchitis, and asthma. The bronchi and right part of the trachea were distinctly congested. If the child's head were pushed backward the child stopped breathing. On slight provocation he had distinct attacks of asthma and diminished respiration on that side. He thought this was a case of enlarged bronchial glands.

Dr. John Howland said that judging from the pictures the thymus was slightly enlarged. An enlarged thymus in children did not necessarily mean status lymphaticus. The term status lymphaticus was usually applied to children dying as the result of an enlarged thymus gland when that was the only pathological sign present and there was no other apparent cause for death. This condition was more common than was usually believed. It seemed that in children dying of status lymphaticus the picture was found because they died so suddenly. Hochsinger said that he examined thirty cases of laryngeal stridor and found an enlarged thymus shadow in each, and he had also examined perfectly healthy children and found an enlarged thymus in a large percentage of them.

Two Cases of Empyema.—Dr. O. M. Schloss presented these cases:

Case I.—This child, three months old, was admitted to Bellevue clinic complaining of cough, fever, and loose bowels. She had been well up to one month before admission. Her condition was diagnosed as bronchitis. On examination it was found that the child had profound anemia and general enlargement of the lymphatic glands. The left side of the chest looked a trifle larger and moved less on respiration than the right. Tactile fremitus was absent on the left side. The apex impulse was not palpable at the usual site, but about three centimeters within the left midclavicular line and corresponded to the fifth interspace. The left side of the thorax was flat on percussion from the angle of the scapula to the costal margin posteriorly and anteriorly from the fourth rib to the costal margin; while above these points the percussion note showed impaired resonance. The signs left little doubt as to the diagnosis, and an exploratory puncture showed thick yellowish pus from which streptococci and *Staphylococcus aureus* were grown. At operation about 120 c.c. of pus was evacuated. Although a simple operation was performed profound collapse followed. After the usual stimulants had been given the child slowly responded and a rapid recovery ensued. The prognosis in this case was at the outset rather bad, as streptococcic empyemas were generally regarded as the most virulent form and there was a general impression that infants under six months died more often than they recovered from their empyema. In this case a simple incision was sufficient, and he feared that had a rib been resected the outcome might have been different, as the shock from the simple operation had been so profound.

Case II.—This patient had an empyema following a pneumonia. He was in the Presbyterian Hospital eight days, and during this time several exploratory punctures were made with negative results. During the past few months the child had improved, had gained in weight, had a good appetite, and slept well. The physical signs of an

empyema were still present but less marked. This patient evidently had an empyema and, although the patient was not operated on, the pus was either removed by lymphatic absorption or by rupture into a bronchus. According to the history the latter was more likely, the drainage being imperfect. Pleural thickening and adhesions had formed and the lung was probably bound down and adherent. The question was, Had this patient bronchiectasis? The scattered areas of bronchial breath sounds, the occasional cavernous quality and the veiled puff, the periodic expectoration of large amounts of pus, the absence of pleural effusion, and the variation in the physical signs at the different examinations were in favor of this diagnosis. It was never possible to examine the patient before and after expectoration, which would have been a great advantage in her diagnosis.

Dr. Eli Long asked if anyone else could report cases of empyema that had not been operated on.

Dr. W. P. Northrup said that if he remembered correctly the diagnosis was old empyema, that the child had spit up the pus and that absorption and retraction had done the rest. The *x*-ray showed nothing. The *x*-ray and needle showed no pus and no operation was attempted.

Dr. Eli Long said that it was interesting to know that the v. Pirquet test in this case was now positive, while two months ago it was negative.

Dr. Schloss stated that the mother had told him that the child had spit up at times as much as a bowlful of material. It seemed probable from the history that operation was not called for.

Dr. Long said that the case was interesting to him because he had the idea that such cases when operated on when under a year old died. If a baby could do as well as this one, it would in the future revise his prognoses in empyema work.

Dr. Northrup said that he had a case only seven weeks old that did as well as this one.

Some Cases of Lisping.—Dr. E. W. Scripture presented some cases which he said might be termed "negligent speech." They were characterized by a lack of precision and correctness in using the muscles of speech, and were due to a kind of mental negligence or inattention. These cases could be readily cured by such comparatively simple methods that the general practitioner could effect cures in the course of regular office treatment.

Sarcoma of the Kidney.—Dr. J. Finley Bell and Dr. S. D. Jessup reported the case of a male infant, four months old, breast fed, who had a congenital sarcoma of the kidney. While these cases were by no means rare, they occurred with sufficient infrequency to make each one interesting. From the history and course of this case, together with autopsy findings, one was justified in making a diagnosis of congenital sarcoma of, or in the region of, the left kidney, its hilum, or ureter, causing obstructive hydronephrosis, multilocular in character. The various loculi corresponded to one or more dilated compartments of the kidney. Dr. Jessup presented the pathologist's report; the diagnosis was spindle celled sarcoma with cystic degeneration.

Dr. Northrup said that while congenital sarcoma was not very common it could not be said to be rare. One peculiarity was that they seemed to grow from a single pole of the kidney, the tumor being so large that the kidney seemed to be grafted on it.

Dr. Bell said that some time ago Dr. Jacobi reported a case of still-birth in which there was found sarcoma of the kidney.

Squint in an Infant Eighteen Months Old.—Dr. W. H. Holzapfel reported this case. The squint was corrected by eyeglasses. The case was one of many similar types with similar results, showing hyperopia to be the cause of convergent strabismus in most cases. The best results were obtained in children. After an eye became more fixed in position, not only glasses but operation was necessary in order to obtain binocular vision.

Dr. J. Finley Bell reported two similar cases occurring in his practice during the past eighteen months. It was to him a satisfaction to know that a young child's eyes could be successfully corrected with glasses.

Dr. Thomas S. Southworth reported the case of a child two and a half years old with squint. The case was referred to a prominent ophthalmologist in a large Western city, who told the parents to bring the child back when it was four or five years old. This was another instance of the fact that the position taken by the best ophthalmologists here had not yet reached the West. It was of the highest importance that such a squint should be corrected early, so that the power of the eye might not be lessened.

Dr. Eli Long said that while the operation for squint in a child was not particularly dangerous it was something that one did not like to undertake, and it was very satisfactory to know that there was some way of avoiding it. Dr. Long then asked Dr. Holzapfel what proportion of cases responded satisfactory to this treatment.

Dr. Holzapfel replied that satisfactory results were obtained in the vast majority of the cases, though comparatively few cases were seen in infants as the children were seldom brought to the ophthalmologists until they were from five to ten years old.

GENITOURINARY SECTION.

Stated Meeting, May 19, 1909.

Dr. Martin W. Ware in the Chair.

Vesical Calculi.—Dr. J. F. Tooker of Hwai Yuen, China, reported on a series of operations for calculi, over seventy in number, which he had removed during the past eighteen months. In China vesical calculi were particularly common in Canton and in the region north of Nanking, and at least 50 per cent. of these patients in the latter region were children, while in 75 per cent. they were under twenty years of age. In a series of 73 cases pus was found in the urine in 54, and 23 of these were under ten years of age. He showed one urethrovesical calculus which he had removed from a boy of eleven years, whose symptoms dated back five years. In reply to a question as to whether the opium habit, in its deleterious effects on the general health, acted as a factor in the production of vesical stone, Dr. Tooker said he did not think so, nor did he discover any parasite which could be held responsible for their prevalence. In nearly all these cases the stones were removed by suprapubic cystotomy, as the speaker said he had had no experience with the crushing method.

Urinary Calculi.—Dr. James R. Hayden showed a large collection of such stones. The first series comprised twenty-eight calculi that were passed from the kidney to the bladder, giving rise to the usual symptoms of renal colic, and then escaped spontaneously from the bladder without giving rise to any symptoms. In a second series of six cases the stones, also of renal origin, passed from the kidney to the bladder, with symptoms of renal colic, and then became impacted in various parts of the urethra, giving rise to either partial or complete retention. In the removal of these stones from the pendulous urethra, the speaker said he had found Ultzmann's urethral scoop very serviceable. External urethrotomy was employed for the calculi lodged in the bulbous-prostatic portions of the canal. Dr. Hayden also showed another series of stones which he had removed from the urinary bladder by the suprapubic route. In two of these cases the calculi had formed around particles of wax introduced into the bladder by sexual degenerates. He also reported a case of multiple

prostatic stones removed post-mortem, and one case where 102 vesical calculi were removed through an evacuating tube. In one case the calculus removed weighed 1,050 grains.

Multiple Vesical Calculi Voided Periodically by a Prostatic.—Dr. Victor C. Pedersen reported this case and showed the specimens. The patient was an old sailor, who had collected about 40 or 50 calculi which he had passed spontaneously during the past two years, these representing about one-third of the total number that he had passed at various times. The patient gave a history of five or six attacks of gonorrhea, for which he had treated himself. An examination in this case showed considerable prostatic hypertrophy. The case was interesting as illustrating how much traumatism the genitourinary organs might be subjected to in some patients without causing serious symptoms.

Dr. Pedersen also showed a calculus which he had removed from a Chinaman by external urethrotomy from behind a midpenile stricture. The operation was done without the aid of an anesthetic, and the man made a rapid recovery. The stone was apparently renal in origin, but the patient gave no history of renal colic.

Dr. Joseph Wiener said that last summer he saw a man seventy-one years old who gave a prostatic history and showed a small stone he had voided the day before he came under observation. Since that time he had been able to void scarcely any urine. A catheter which was introduced was obstructed about half an inch from the meatus, due to the presence of an impacted calculus. Upon removing this a second calculus was found higher up. This was also removed, and it was then possible to pass a catheter into the bladder. Upon subsequently opening the bladder, twenty additional stones were found, some in the bladder and some partly imbedded in the prostate.

Prostatic Calculus.—Dr. Antonio Fanoni reported this case and showed the specimen. The patient was an Italian, eighteen years old, who was sent to the Italian Hospital in December, 1908, suffering from frequent urination and slight hematuria. The searcher in the prostatic urethra elicited the presence of a stone, which was removed through a perineal incision. The stone was located in the prostatic urethra.

Dr. Hayden thought it was unusual to find such a large and rough stone in the prostatic region without giving rise to more pronounced symptoms. He inquired regarding the condition of the prostatic gland, and also that of the sexual functions; whether the latter had been affected as the result of carrying the stone?

The chairman, Dr. Ware, asked whether the stone was perceptible per rectum? Also, whether the stone was actually lodged in the prostatic region or in the substance of the gland?

Dr. Fanoni, in closing, said the prostate was completely atrophied, so that nothing remained but a shell. The stone could not be felt from the rectum, but its enucleation necessitated a prerectal incision. It was a large stone of the prostatic urethra, rather than of the prostate itself. It was a typical mulberry calculus, probably originating in the bladder.

Ureterectomy for a Calculus Embedded in a Dead Ureter.—By Dr. A. V. Moschowitz. The patient was a girl nineteen years old, who was admitted to the service of Dr. Arpad G. Gerster at the Mt. Sinai Hospital in February, 1908, with symptoms indicating the presence of a calculus in the urinary tract. An *x*-ray was taken, which showed a faint shadow along the course of the right ureter, about an inch from its vesical end. She was then cystoscoped, and a ureteral catheter was easily passed through the ureter which was supposed to be the seat of a stone. After further study of the case, Dr. Gerster exposed the ureter, but failed to find a calculus. The corresponding kidney was then exposed, but nothing was found to account for the patient's symptoms. Subsequent to this operation the patient developed a suppurative condition, with high temperature, and as a matter of necessity the kidney was removed. At the time of this operation a wax-tipped catheter was passed into the ureter from above, and upon its removal it showed distinct scratch-marks, giving evidence that it had come in contact with a calculus. The patient refused further operative interference until February, 1909. An *x*-ray was again taken, which showed a shadow in the exact location of that shown on the previous picture. The ureter was again exposed, and a calculus found embedded within it, about half an inch from the vesical outlet. Complete ureterectomy was performed. The patient made an uneventful recovery from the operation, and had been free from symptoms since that time.

Dr. Ware recalled an exactly parallel case, where a ureteral stone which was seen by the *x*-ray could not be found on operation. This was followed by a fistula, and several months later the corresponding kidney was exposed and drained in order to divert the urine. This was promptly followed by healing of the ureteral fistula. A year later the patient had a recurrence of his symptoms, and the stone was again located in identically the same spot as before by means of the *x*-ray. A second operation for its removal was undertaken, and this proved successful.

Ureterotomy for Supposed Ureteral Calculus; Nephrectomy.—By Dr. Moschowitz. The patient was a young man who came to the hospital about three years ago with vague and indefinite symptoms that led to an exploratory laparotomy. The incision was made rather high up, and there was removed at that time a chronically diseased appendix. Subsequent to this operation the patient still complained of indefinite pain localized in the right half of the abdomen. The urine showed blood under the microscope, and upon *x*-ray examination a peculiarly shaped shadow was observed in the lower ureter, opposite the spine of the ischium. A diagnosis of ureteral calculus was made and an operation advised. The ureter was exposed and thoroughly explored through the usual extraperitoneal incision, with negative results. A small incision was then made into the ureter, through which a bougie could be passed into the bladder. As the result of this operation a ureteral fistula developed, with subsequent involvement of the kidney, necessitating a nephrectomy. At the time of its removal the kidney presented the appearance of a large pus sac, with very little secreting tissue left. There was pus in the pelvis and parenchyma of the organ, and a nephrectomy seemed to be the wisest thing to do.

Calculi from Both Kidneys and Calculus from Ureter Removed at Two Different Operations.—Dr. Moschowitz showed the specimens and the *x*-ray pictures in this case. The patient complained of symptoms referable to the urinary tract, and an *x*-ray showed a calculus in the right kidney. After the removal of the stone the patient developed symptoms referred to the opposite kidney. An *x*-ray showed that these were due to stone in the left ureter. This was passed spontaneously. Subsequently, the patient returned and complained of pain again referable to the left kidney. A third *x*-ray picture showed an irregularly shaped calculus in the left kidney. This stone was removed about a month ago, and the patient made an uneventful recovery.

Loss of Sexual Power Following Operation for Rectal Fistula.—Dr. Forbes R. McCreery reported the case of a man, fifty-six years old, who was operated on about five months ago for a rectal fistula on the left side. Since that time he had suffered from incontinence of feces and a marked impairment of his sexual power. His

erections were very feeble and transitory, and the penis showed a tendency to curve towards the left. The incision that was made at the operation was evidently quite a deep one, and in addition to cutting the fistula, the cautery was employed.

Dr. Joseph Wiener said he was at a loss to understand why impairment of sexual power should have followed the operation for fistula in the case shown by Dr. McCreery, no matter how high up the incision was made. It was not an uncommon procedure to excise the rectum above the border of the coccyx, and even remove the coccyx itself, without resulting impotence.

Stone in Pelvis of Kidney.—Dr. Joseph Wiener reported this case and showed the specimen. The patient was a married woman, twenty-five years old, who was admitted to the Mount Sinai Hospital on March 13, 1907, with the history that a year prior to that time she had an attack of cramplike pain in the right side of the back, radiating to the right labium. Since then she had had several similar attacks, of growing intensity. She had never been jaundiced. The pain did not radiate to the shoulder. Following these attacks she would sometimes have hematuria. Two *x*-ray pictures were taken, one in October, 1906, and the second in March, 1907; both of these showed a stone in the pelvis of the right kidney. Operation, March 14, 1907. The right kidney was exposed through an oblique incision, and by manual compression a stone could be felt in the pelvis. A one-inch incision was then made through the cortex into the pelvis of the kidney and the stone removed. The kidney was sutured and the abdominal wound closed, leaving a small gauze drain down to the kidney. The patient left the hospital twenty days after the operation with a two-inch sinus, which soon healed.

Kidney and Calculi from Pyonephrosis.—Dr. Wiener showed these specimens, which were removed from a woman sixty-nine years old, who gave a history of continuous pyuria dating back twenty years, the urine being loaded with pus. The cystoscope showed an approximately normal bladder. Urine obtained from the left ureter contained about 50 per cent. pus. The right ureter could not be examined at the time. A diagnosis was made of left pyonephrosis, and an operation was advised, but refused. Six weeks later the patient had an attack of almost complete anuria, lasting twenty-four hours. She was removed to the hospital, and upon incision the left kidney was found to be enormously enlarged. Upon attempting to incise the kidney it was found very dense, with its pelvis and calyces filled with a hard, cement-like substance which it was almost impossible to remove. The kidney was thereupon removed. The anuria persisted, and the patient died twenty hours later. No post-mortem.

Treatment of Measles.—M. J. Hallé says that while measles is not a severe disease in the family where isolation is possible and hygiene can be carried out, it is a fatal disease where this is not possible. The important measures in its treatment are all hygienic; isolation in a moderately light room, with plenty of fresh air, daily spongings and changing of the clothes, washing of the eyes with a mild boracic acid lotion, and cleansing of the nose, throat, mouth, and vulva. Diet should be bland and purgatives avoided, since diarrhea is a frequent symptom. The cough should not be abolished, but softened by ammonia. The child should remain about ten days in bed. In complicated cases prompt treatment is needed. When there are symptoms of suffocation cold baths are useful. In the rare hemorrhagic cases tonics and strychnine are indicated. When there is hyperpyrexia warm baths may be substituted for cold, according to the reaction. In bronchopneumonia, or when it is threatened, warm baths or compresses should be used. In adynamic forms mustard baths are valuable. Diffusible stimulants are demanded and injections of camphorated oil are valuable. Laryngitis demands warm steam sprays in the room. Ear complications should be forestalled by warm instillations into the ears.—*La Presse Médicale.*

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

Medical Examining Board of Virginia.

June 22, 23, 24, and 25, 1909.

ANATOMY AND EMBRYOLOGY.

1. Describe briefly the nasal cavity and the bones which enter into its formation.
2. Describe the sacrum and tell what passes through the openings in it.
3. (*a*) What membranes envelop the brain? (*b*) What processes are formed by the outer one?
4. Name the bones which form the foot, and give the articulation of each.
5. Give the course and relations of the ureter in the female pelvis.
6. What nerves supply the tongue?
7. Name the muscles attached to the scapula.
8. Describe the abdominal aorta. Name its branches and give their general distribution.
9. Give boundaries and contents of Scarpa's triangle.
10. Give the course and relations of the colon.

PHYSIOLOGY.

1. Describe the digestive processes which take place in the mouth and stomach.
2. What changes take place in the blood in its passage through the lungs? What is tidal air and residual air?
3. Which portion of the glandular structure of the kidney excretes the salts, and which the watery constituent of the urine? Describe normal urine.
4. What nerves form the solar plexus, and what organs (viscera) does it supply?
5. Give the origin, function, and distribution of the seventh cranial nerve.
6. Name the varieties and respective functions of the glands of the skin. Where is the breathing center located?

MATERIA MEDICA.

1. Name the preparations of manganese. Give dose and physiological action of each preparation.
2. Describe the physiological effects of emetine.
3. Compare the effects of hyoscyamus, belladonna, and stramonium.
4. Describe the toxic action of and give the antidotes to the salts of mercury.
5. What is ergot? What are its effects upon the parturient uterus? Give dose of the fluid extract.
6. Name the principal alkaloids of opium. Compare their effects and give the antagonists to opium poisoning.

CHEMISTRY.

1. Describe iodine. From what source is it chiefly obtained? What are its uses? Give a simple test for iodine.
2. What elements are known as the alkali-metals? Give some of their common properties.
3. Give formulæ of three official potassium salts, indicating the uses of each.
4. To what does potassium permanganate owe its disinfectant properties? Explain this reaction.
5. Give the formulæ of mercurous chloride and mercuric chloride. Describe the difference between them as regards their physical appearance and medicinal properties and uses.
6. Give formula of chloral hydrate. How is it prepared? Give uses.

TOXICOLOGY.

1. Give symptoms and treatment of acute arsenical poisoning.
2. Give symptoms and treatment of chronic arsenical poisoning.
3. What is trichiniasis? How produced, and how may it be recognized?

MEDICAL JURISPRUDENCE.

1. Give medicolegal definition of wound.
2. Describe following kinds of wounds: Incised, punctured, lacerated, contused. What is coma? Mention three causes of coma.

THERAPEUTICS.

1. What are the therapeutic uses of the silver preparations?
2. What are the indications for the use of strophanthus, of sparteine sulphate?
3. Give the methods of administering turpentine, the indications for its use, and the caution to be observed in its application.

4. Give therapeutic uses of salicylic acid.
5. Give the drugs applicable in the treatment of influenza and state how they should be used.
6. Give the general therapy of the preparations of ammonia.

PRACTICE, ETIOLOGY, AND DIAGNOSIS.

1. What is parotis? Give symptoms. State most usual complications and how managed.
2. Give cause and treatment of myxedema.
3. Give symptoms, appearance, and treatment of herpes zoster.
4. Give physical and clinical symptoms of chronic cardiac dilatation.
5. What inferences should be drawn from persistent scanty urination?
6. What are the two varieties of jaundice, and to what is each due?
7. How would you distinguish between ascites and other abdominal enlargements?
8. Give symptoms, dangers, and management of arteriosclerosis.
9. What are the earliest noticeable indications of tuberculous invasion?
10. In what condition is gastric lavage indicated, and when is it contraindicated?
11. Differentiate between tetanus and tetany.
12. In what condition do we find: (*a*) temporary, and (*b*) persistent, enlargement of the lymphatic glands.

OBSTETRICS, GYNECOLOGY, AND PEDIATRICS.

1. (*a*) How many cases of labor have you delivered? (*b*) How many have you seen delivered? (c) Describe the delivery of the most difficult case you have seen.
2. Inevitable abortion at the fourth month of pregnancy: (*a*) Diagnosis. (*b*) Management in detail.
3. Define the following: (*a*) hydatidiform mole; (*b*) Placenta succenturiata; (*c*) Caput succedaneum; (*d*) Vernix caseosa; (*e*) Melena.
4. Management of the third stage of labor.
5. Active treatment of (*a*) Sapremia; (*b*) Septic endometritis.
6. Necessity for and the technique of repairing second degree lacerations of the perineum following labor.
7. Cancer of breast: (*a*) Early diagnosis; (*b*) Indications for operation.
8. Radical operation for the cure of cancer of breast: (*a*) Technique; (*b*) What constitutes a permanent cure?
9. Pertussis: (*a*) diagnosis; (*b*) complications; (*c*) prognosis; (*d*) prophylaxis.
10. Acute rheumatic infection in children; (*a*) manifestations; (*b*) treatment.

SURGERY.

1. What is meant by physiological and pathological hypertrophy, physiological and pathological atrophy?
2. What is meant by infection, and mention chief sources of infection?
3. Mention the chief complications of gonorrhea.
4. Define asepsis, antisepsis, disinfectant, sterile deodorant.
5. Differentiate fracture near a joint from a dislocation.
6. What is Pott's fracture, and how should it be dressed?
7. After a clean abdominal section, what would lead you to suspect infection?
8. Give diagnosis of empyema and treatment for same.

PATHOLOGY.

1. Name the varieties of degeneration. Name the form of degeneration that tubercle undergoes in chronic cases of tuberculosis.
2. What is infection? How do bacteria gain entrance into the body? What is suppuration?
3. Give the etiology and pathology of acute endocarditis. What are its results if patient survives the acute attack?
4. What is endarteritis (endoarteritis)? What is endarteritis obliterans, and what are its ultimate results to the tissues supplied?
5. What is granulation tissue, and under what conditions is it formed?
6. Name the blood changes in leukemia. What is the condition of the spleen and lymphatic glands in this disease?

BACTERIOLOGY.

1. Explain the terms obligate aerobe and facultative anaerobe. Define the terms germicide, disinfectant, antiseptic, and aseptic.
2. Describe (tell all you know about) the tubercle bacillus.
3. Name a motile, pathogenic microorganism. To what is the power of motion in certain bacteria due? Classify the most common pyogenic microorganisms. Name a pathogenic diplococcus.

NEUROLOGY.

1. Define the terms neurasthenia, psychasthenia, tic, and tonic and clonic as applied to the character of spasms.
2. Give the symptomatology of acute anterior poliomyelitis (infantile paralysis).
3. Give the diagnosis and treatment of locomotor ataxia (tabes dorsalis).

HYGIENE.

1. Name the dangers attendant upon the use of spring and well water for drinking purposes. What precautions should be taken to protect the water from these sources?
2. Describe the hygienic treatment of pulmonary tuberculosis.
3. Name the diseases of animals that are communicable to man. Name the chief impurities of the air in large cities.

HISTOLOGY.

1. Give the histological structure of a nerve.
2. Give the histological structure of Peyer's patches and that of an artery.

LARYNGOLOGY.

1. What symptoms would cause you to suspect adenoids in children?
2. Define aphonia, and give its common causes.
3. What is the essential cause of diphtheria? What of pseudomembranous or true croup? Give the most important points in differential diagnosis between follicular tonsilitis and diphtheria.

RHINOLOGY.

1. State four local and four general causes of epistaxis.
2. What structures are involved in hypertrophic catarrh? Give symptoms and treatment. Give symptoms and treatment of chronic atrophic catarrh. What is it usually called, and why so called?

OPHTHALMOLOGY.

1. Define ptosis; strabismus; diplopia; myopia; hypermetropia; presbyopia; chalazion.
2. State etiology, symptoms, and treatment of acute conjunctivitis; also its common name when it becomes contagious.
3. Give etiology, symptoms, and treatment, both preventive and remedial, of ophthalmia neonatorum.

OTOLOGY.

1. Give three methods of removing foreign bodies or impacted wax from the ear.
2. Give etiology, symptoms, and treatment of acute mastoiditis; name three of its most common and serious results.

ANSWERS TO STATE BOARD EXAMINATION QUESTIONS.

MEDICAL EXAMINING BOARD OF VIRGINIA.

June 22, 23, 24, and 25, 1909.

ANATOMY AND EMBRYOLOGY.

1. The *nasal cavities* are two large, irregular shaped cavities, situated one on each side of the middle line of the face, extending from the base of the skull to the roof of the mouth, and separated from each other by a median septum. They open in front by the anterior nares, with the face; and behind, by the posterior nares, with the nasopharynx. They are wider below than above. *Bones entering into their formation* are: Frontal, sphenoid, ethmoid, lacrymal, nasal, palate, superior maxillary, vomer, and inferior turbinated.

2. For description of sacrum, see any text-book on anatomy. The sacral nerves pass through the foramina in the sacrum.

3. (*a*) *Membranes which envelop the brain:* Dura, arachnoid, and pia. (*b*) *The processes of the dura:* Falx cerebri, falx cerebelli, tentorium cerebelli, and diaphragma sellæ.

4. The *os calcis* articulates with the astragalus and cuboid; the astragalus with the tibia, fibula, os calcis, and navicular; cuboid with the os calcis, external cuneiform, fourth and fifth metatarsals; navicular with the astragalus and third cuneiform; internal cuneiform with the navicular, middle cuneiform, first and second metatarsals; middle cuneiform with the navicular, internal and external cuneiform, and second metatarsal; external cuneiform with the navicular, middle cuneiform, cuboid, and second, third, and

fourth metatarsal; the *metatarsals* articulate with the tarsal bones by one extremity, and by the other with the first row of phalanges; the number of tarsal bones with which each metatarsal articulates is one for the first, three for the second, one for the third, two for the fourth, and one for the fifth; the *phalanges* of the first row, with the metatarsal bones behind and second phalanges in front; the second row of the four outer toes, with the first and third phalanges; of the great toe, with the first phalanx; the third row of the four outer toes, with the second phalanges.

5. *The ureter, in the female pelvis,* runs downward in front of the sacroiliac synchondrosis, then upon the Obturator internus and its fascia, lying behind and below the Psoas; it then enters the uterovesical fold below the obliterated hypogastric artery. It passes down parallel with the cervix uteri and the upper part of the vagina, behind the uterine artery, through the uterine plexus of veins, and below the broad ligament; it crosses the upper third of the vagina to reach the vesicovaginal interspace, and enters the bladder opposite the center of the vagina.

6. *The nerves which supply the tongue* are: (1) The lingual branch of the inferior maxillary division of the trigeminus (sensation); (2) chorda tympani (taste); (3) lingual branch of the glossopharyngeal (taste and sensation); (4) hypoglossal (motor).

7. *The muscles attached to the scapula* are: Subscapularis, Supraspinatus, Infraspinatus, Trapezius, Deltoid, Omohyoid, Serratus magnus, Levator anguli scapulæ, Rhomboideus major and minor, Triceps, Teres major and minor, Biceps, Coracobrachialis, and Pectoralis minor.

8. The *abdominal aorta* begins at the aortic opening in the diaphragm and extends to left side of the fourth lumbar vertebra, where it divides into the two common iliacs. It lies to the left side of the inferior vena cava.

Its branches are: (1) *Phrenic,* to diaphragm. (2) *Celiac axis,* to stomach, liver, and spleen (also to esophagus, pancreas, and omentum). (3) *Superior mesenteric,* to small intestine, ascending and transverse colon. (4) *Inferior mesenteric,* to descending colon, sigmoid flexure, and rectum. (5) *Suprarenal,* to suprarenal body. (6) *Renal,* to kidney and ureter. (7) *Spermatic* or *ovarian,* to testes or ovaries, and round ligament. (8) *Lumbar,* to muscular wall and skin of abdominal cavity. (9) *Middle sacral.*

9. *Scarpa's triangle* is bounded *above* by Poupart's ligament, *externally* by the sartorius, and *internally* by the inner margin of the adductor longus; its *apex* is formed by the junction of the adductor longus and sartorius. The *floor* is formed, from without inward, by the iliacus, psoas, pectineus, adductor brevis, and adductor longus. *Contents:* The femoral vessels pass from about the center of the base to the apex, the artery being on the outer side of the vein; the artery gives off the superficial and profunda branches, and the vein receives the deep femoral and internal saphenous; the anterior crural nerve lies to the outer side of the femoral artery; the external cutaneous nerve is still further external, lying in the outer corner of the space; just to the outer side of the femoral artery, and in the sheath with it, is the crural branch of the genitocrural nerve. At the apex the vein (which at the base was internal to the artery) lies behind the artery. The triangle also contains fat and lymphatics.

10. The colon is divided into ascending, transverse descending, iliac, and pelvic.

The *ascending colon* extends from the cecum to the under surface of the liver to the right of the gall-bladder, where it turns to the left, forming the *hepatic flexure.* It lies in the right iliac and right hypochrondriac regions. The peritoneum covers the anterior and lateral surfaces. Length, 8 inches. *Relations.—In front:* The convolutions of the ileum; *behind:* Iliacus, quadratus lumborum, outer side of right kidney.

The *transverse colon* passes from right to left, from the gall-bladder to the spleen. It forms an arch, convex anteriorly and below: the *transverse arch of the colon.* It is entirely surrounded by peritoneum, which is attached posteriorly to the spine, forming the mesocolon. Length, 20 inches. *Relations.—Above:* Liver, gall-bladder, large curvature of stomach, lower end of spleen; *below:* small intestines; *anteriorly:* anterior layers of great omentum, anterior abdominal wall; *posteriorly:* right kidney, second part of duodenum, transverse mesocolon, pancreas, and small intestines.

The *descending colon* passes from the end of the transverse colon by a bend, *the splenic flexure.* Between the splenic flexure and the diaphragm, opposite the tenth left rib, is a fold of the peritoneum, the *costocolic ligament,* which slings up the spleen. The gut then passes downward to the iliac crest, ending in the iliac colon. The peritoneum invests its anterior and lateral surfaces. Length, 4 to 6 inches. *Relations.—Behind:* left crus, left kidney, quadratus lumborum, and psoas; in *front:* small intestines; *inner side:* outer border of left kidney.

The *iliac colon* is continuous with the descending colon at the left iliac crest, and ends at the inner border of the left psoas. Peritoneum invests its anterior and lateral surfaces; it has no mesentery. Length, 5 to 6 inches. *Relations.—In front:* Small intestines; when distended, the anterior abdominal wall; *behind:* left iliopsoas.

The *pelvic colon* extends from the inner border of the psoas to the level of the third sacral vertebra. Length, 16 or 17 inches; very variable. It has an extensive mesentery. *Relations.*—Passing over left brim of pelvis, it crosses the left external iliac vessels and left ureter, and passes to right margin of pelvis, resting on bladder in male and uterus in female; above lie coils of small intestine. It then turns back to midline on posterior wall of pelvis, and, forming a second bend, descends to end in the rectum. —(From *Aids to Anatomy.*)

PHYSIOLOGY.

1. *In the mouth:* The food is crushed, mixed with saliva, and reduced to a pulp; it is rendered slightly alkaline, and a small amount of starch is converted into maltose; the proteids and fats are unaltered. *In the stomach,* where the contents are rendered acid, conversion of starch into sugar ceases, connective tissue of fats is dissolved and fats are set free. Proteids are dissolved and peptones formed. The albuminous foods are dissolved for the most part, and a grumous mixture of peptones, liquid fats, and starches is formed, which is termed chyme, and is gradually passed through the pylorus into the intestine.

2. In its passage through the lungs, the blood (1) becomes cooled; (2) becomes a brighter red color; (3) gains oxygen (about 10 or 12 volumes); (4) loses carbon dioxide (about 7 volumes).

Tidal air is the air which is constantly passing in and out of the lungs during ordinary calm respiration. It measures about 30 cubic inches. *Residual air* is the air which still remains in the lungs after the deepest expirations. It measures about 100 cubic inches.

3. The salts and also the watery constituent of the urine are both excreted by the glomerulus of the kidney.

Urine is a yellowish liquid, acid in reaction, specific gravity from about 1015 to 1025. About fifty ounces are excreted in twenty-four hours. Its normal constituents are: Water, urea, uric acid, urates, hippuric acid, kreatinin, xanthin, hypoxanthin, sulphates, chlorides, and phosphates of sodium and potassium, phosphates of magnesium and calcium, nitrogen, and carbon dioxide.

4. The solar plexus is formed by the great, small, and least splanchnic nerves of both sides, and by the right pneumogastric nerve; the two semilunar ganglia, and other ganglia, also enter into its composition. It supplies all the viscera in the abdominal cavity.

5. The *seventh cranial or facial nerve* has its superficial origin in the upper end of the medulla oblongata, in the groove between the olivary and restiform bodies. It passes "forward and outward to enter the internal auditory meatus; it lies upon a groove on the auditory nerve, with portio intermedia of Wrisberg between, and at the bottom of the meatus it enters the aqueductus Fallopii, along which it runs first outward between cochlea and vestibule as far as hiatus Fallopii; then backward in internal wall of tympanum, just above fenestra ovalis, at the turn presenting a swelling, the *geniculate ganglion;* and finally it passes downward, to emerge from the bone at the stylomastoid foramen; it then passes outward and forward in the parotid, dividing behind the ramus of the jaw into *temporofacial* and *cervicofacial* branches, which further subdivide and intercommunicate, forming the *pes anserinus.*"—(*Aids to Anatomy.*)

Function: The facial nerve is the motor nerve of the muscles of expression, also of the platysma and the buccinator; it also supplies the muscles of the external ear, the stylohyoid, and the posterior belly of the digastric. Through the chorda tympani it is a nerve of taste and a vasodilator of the vessels of the submaxillary and sublingual glands.

6. The glands connected with the skin are the sweat glands and the sebaceous glands. The *sweat glands* secrete the sweat or perspiration, whose function is: (1) Excretion of water, carbon dioxide, and urea; (2) to cool the surface of the body; and (3) to regulate the body heat. The *sebaceous glands* secrete sebrum, whose function is: To lubricate the skin and keep it flexible; to prevent undue absorption, and to keep the skin from getting macerated.

The *respiratory center* is in the medulla, at the apex of the calamus scriptorius. (Subsidiary centers are also found in the spinal cord.)

MATERIA MEDICA.

1. *Preparations of manganese:* (1) Precipitated manganese dioxide; dose, gr. iv. It has an astringent action. (2) Manganese hypophosphite; dose, gr. iij. It has little or no physiological action. (3) Manganese sulphate; dose, gr. iv. Its action is first astringent, later emetic and purgative. (4) Potassium permanganate; dose, gr. j. It is a deodorant and disinfectant; also irritant.

2. *Emetine* is, in small doses, a gastric stimulant; it then acts on the vomiting center in the medulla, and is thus an indirect emetic; it produces but slight nausea and depression; it stimulates the bronchi to increased secretion, moderately depresses the circulation, is a slight diaphoretic, and acts on the liver as a direct cholagogue.

3. "The action of hyoscyamus is almost identical with that of belladonna and stramonium. The following are the chief points of difference: (1) Hyoscyamus contains in addition hyoscine in minute quantities. This is a powerful cerebral and spinal sedative, and therefore the excitation and delirium occasioned by the atropine in belladonna are not so evident when hyoscyamus is given; indeed, that may, owing to the hyoscine in it, distinctly depress the higher functions of the brain. The heart is not quite so powerfully affected by hyoscyamus as by belladonna, for hyoscine has a comparatively feeble cardiac influence. Still, it is, of course, affected by the hyoscyamine, which acts like atropine. (2) Hyoscyamus increases the peristaltic contractions of the intestines more powerfully than belladonna, and at the same time it is more efficient in relieving the griping of other purgatives. (3) Hyoscyamus has a more markedly sedative action on the urinary unstriped muscle than belladonna."—(White & Wilcox's *Materia Medica, etc.*)

4. The toxic action of the salts of mercury is indicated by: Pain in mouth and stomach, gastroenteritis, hematemesis, bloody stools, scanty and albuminous urine with casts, salivation.

Antidote: White of egg in moderate quantity, followed by an emetic.

5. *Ergot* is the sclerotium of the claviceps purpurea. It excites contractions in the parturient uterus. The dose of the fluid extract is thirty minims.

6. The *principal alkaloids of opium* are: Morphine, codeine, thebaine, narcotine, narceine, papaverine. In *soporific effects*, beginning with the most powerful, they rank: Narcotine, morphine, codeine; in *tetanizing action:* Thebaine, papaverine, narcotine, codeine, morphine; in *toxic action:* Thebaine, codeine, papaverine, narceine, morphine, narcotine.

Antagonists: Potassium permanganate, atropine, caffeine, and strychnine.

CHEMISTRY.

1. *Iodine* is a solid crystalline substance, having a blue-gray color and metallic luster; the vapor has a violet color and a peculiar odor, and is very irriating to the eyes and nose. It stains the skin, and is poisonous. It is only slightly soluble in water. It is obtained from seaweed.

Test for iodine: Add starch paste; in the presence of iodine it becomes blue.

2. The *alkali metals* are: Lithium, sodium, potassium, rubidium, cesium (and silver). They are all solids, univalent; their hydroxides are more or less alkaline and are basic; they form one chloride and one or more oxides.

3. Potassium iodide. KI. Potassium permanganate, $K_2Mn_2O_8$. Potassium chlorate, $KClO_3$. The first is used in the third stage of syphilis, gonorrheal rheumatism, aneurysm, pleurisy, asthma, pericarditis. The second is used as a disinfectant, deodorant, and antiseptic. The third is used in sore throat, tonsillitis, and stomatitis.

4. Potassium permanganate is a very active oxidizing agent, and its action as a disinfectant is due to the oxidation of the organic matter with which it comes in contact. The splitting up of potassium permanganate and the prompt liberation of the oxygen is shown in the following equation: $2K_2Mn_2O_8 + 2H_2O = 4MnO_2 + 4KHO + 3O_2$.

5. *Mercuric chloride*, $HgCl_2$, corrosive sublimate, is heavy, white, and crystalline; it has a strong, acrid, styptic taste and is soluble in water, in alcohol, and in ether; it is decomposed by exposure to light. It is used as a disinfectant, antiseptic, antiparasiticide, and as a cholagogue.

Mercurous chloride, Hg_2Cl_2, calomel, is a heavy, white powder, amorphous, tasteless, and odorless; it is insoluble in cold water and in alcohol, and very slightly soluble in boiling water; when exposed to the light it becomes discolored (first yellow, then gray) and partially decomposed; it sublimes without fusing; it is incompatible with the mineral acids, with the alkaline chlorides, bromides, and iodides. It is used as a laxative, purgative, diuretic; in cases of vomiting, liver congestion or cirrhosis, and as a dusting powder.

6. *Chloral hydrate.* Formula, $CCl_3CH(OH)_2$. It is prepared by adding a little water to chloral. It is used as a hypnotic and sedative; as a solvent for resins, starch, etc.; also in alcoholism, mania, high arterial tension, tetanus, and strychnine poisoning.

TOXICOLOGY.

1. The *symptoms of acute arsenical poisoning:* Nausea and faintness, severe burning pain in the stomach, persistent vomiting of matters, sometimes brown or gray, or streaked with blood, or green; purging, and cramps in the legs. *Treatment:* Induce vomiting, by zinc sulphate; use stomach tube. The chemical antidote is freshly prepared ferric hydroxide. The ferric hydroxide changes the arsenic into ferrous arsenate, which is nonpoisonous.

2. *Symptoms of chronic arsenical poisoning:* Inflammation of the conjunctivæ, with intolerance of light. Irritation of the skin, accompanied by an eruption (eczema arsenicale); local paralyses; great weakness and emaciation; exfoliation of the cuticle and falling out of the hair. *Treatment:* Remove the patient from the exposure and treat the symptoms as they arise; potassium iodide has been recommended.

3. *Trichiniasis* is the condition resulting from eating pork containing *Trichina spiralis.* It is characterized by gastrointestinal irritation, diarrhea, colicky pains, vomiting, fever, sweating, edema of the face and eyelids, great prostration, muscular soreness, emaciation, pronounced leucocytosis, especially increase of the eosinophiles. The trichina may be found in pieces of muscle excised for purposes of examination, or in the stools.

MEDICAL JURISPRUDENCE.

1. A *wound* (medicolegal) is any injury or lesion caused by mechanical or chemical means.

2. *Incised wounds* are made by sharp-cutting instruments; the hemorrhage is free, the wound gapes, there is no bruising of the margins. *Punctured wounds* are deep wounds with a small orifice; they are made by narrow instruments. *Lacerated* and *contused wounds* are made by blunt instruments and by crushing; the soft parts are torn, the edges are bruised and ragged, the deep parts are infiltrated with blood; there is little free bleeding.

Coma is a condition of profound insensibility, chiefly due to a changed condition of the brain. *Three causes of coma:* Apoplexy, opium, alcohol.

THERAPEUTICS.

1. *Therapeutic uses of silver preparations:* As a caustic; for septic processes, boils, and phlebitis; for gonorrhea; for bedsores; in gonorrheal ophthalmia; also as a prophylactic; in dysentery or diarrhea; for ulcers of mouth, stomach, or intestines.

2. *Indicotions for strophanthus:* As a cardiac stimulant; in mitral or aortic obstruction; in cardiac dilatation; palpitation; alcoholism; exophthalmic goiter; nephritis; when heart action is feeble but rapid, and accompanied by low arterial tension; in general, same as digitalis.

Indications for sparteine sulphate: As a diuretic, in cardiac or renal dropsy; also in uncompensated mitral or other cardiac lesions.

3. *Turpentine can be administered:* Locally, as a liniment, as a stupe, by enema, in emulsion, in capsules, on cut sugar, by inhalation, as a spray. *Indications:* As a rubefacient or counterirritant; sciatica, lumbago, neuralgia, chronic rheumatism, sprains, dysentery, hemorrhage of intestines; as a vermifuge against tapeworm; chronic bronchial affections and chronic affections of the genito-urinary tract. *Caution:* Too large doses may produce gastroenteritis, diarrhea, vomiting, suppression of urine, hematuria, strangury; it acts, in toxic doses, as a narcotic poison.

4. *Therapeutic uses of salicylic acid:* "Externally as antiseptic and stimulating applications and for the checking of abnormal perspiration; also in parasitic and other skin diseases. Internally, rheumatic fever (in which it seems to act as a specific); gout; migraine; sciatica; diabetes; cholelithiasis."—(Wilcox, *Materia Medica.*)

5. *For influenza:* The following (among many) have been recommended: Ammonium chloride, alkaline drinks, antipyrin, antiseptics, aperients, arsenic, bismuth, camphor, chloroform, Dover's powder, heroin, hydrocyanic acid, morphine, phenacetin, quinine, salicin, strychnine, aconite, sweet spirit of niter, alcohol, belladonna, bromides, cannalis indica, chloral or sulphonal, ergot.

6. AMMONIUM PREPARATIONS.—*Externally:* Rubefacient, vesicant, for bites of insects. *Internally:* As a gastric,

cardiac, or general stimulant; as an expectorant; hepatic disorders; muscular rheumatism; diaphoretic and diuretic.

PRACTICE, ETIOLOGY, AND DIAGNOSIS.

1. *Symptoms of parotitis:* Chilliness, malaise, moderate fever, pain and swelling of parotid gland, which becomes tender and elastic, but shows no fluctuation; deglutition and mastication are painful; both sides may be affected. *Complications:* Unilateral orchitis, which may be followed by atrophy of testicle; in the female, mastitis or edema of vulva or ovaritis. *Management:* Keep patient in bed; isolate him; salines, hot fomentations, and antiseptic mouth wash. The orchitis will need rest, suspension, and an application of guaiacol ointment or lead and laudanum; afterward mercury and belladonna ointment.

2. MYXEDEMA.—*Cause:* Loss of function of thyroid gland; heredity is supposed to have some influence; it is most common in women. *Treatment:* Keep patient warm, give nourishing food, and administration of sheep's thyroid.

3. HERPES ZOSTER.—*Symptoms and appearance:* Malaise, slight fever; vesicles, in cluster, and on inflammatory base, usually along the course of intercostal nerves, but may be in other locations; it occupies areas which represent the distribution of nerve fibers that enter a single posterior root ganglion; as a rule it is unilateral and accompanied with sharp neuralgic pain. *Treatment:* Zinc phosphide, morphine, and phenacetin have been given; locally, menthol or collodion may be applied.

4. In *cardiac dilatation:* "The symptoms are those of *failing circulation:* precordial anxiety, palpitation, headache, vertigo, syncope, pallor, cough, dyspnea, venous congestion, and dropsy. The cardiac *impulse* is feeble and diffused, and usually displaced to the left. The area of cardiac *percussion-dullness* is increased. The *first sound* is weakened in correspondence with the disproportion between the enlargement of the cardiac chambers and the thickness of their walls; the *second* is little changed. If the dilatation has been great enough to so enlarge the orifices or weaken the muscles that the valves are no longer competent to effect complete closure, regurgitant murmurs may be developed, even in the absence of structural alterations in the valves. Such murmurs are usually rather soft and may be inconstant. The *action* of the heart may be rapid and irregular. The *pulse* is small and soft."

5. Persistent, scanty urination may denote: Heart disease, with broken compensation; degeneration of cardiac muscle; parenchymatous nephritis; chronic diseases of the respiratory apparatus; chronic uterine or liver disease; mechanical obstructions, such as compression of the ureters by tumors, or an enlarged prostate gland.

6. The two varieties of jaundice are (1) obstructive and (2) nonobstructive, or toxemic.

Obstructive jaundice may be due to: Gastroduodenal catarrh; catarrh of the bile ducts; lodgment of gallstones or round worms in the common duct; pressure on or closure of the duct by tumor of the liver, stomach, kidney, omentum, and especially of the pancreas; and new growths or cicatricial tissue producing stricture or obliteration of the lumen of the duct. *Nonobstructive or toxemic jaundice* may be due to: "Influenza, malaria, pneumonia, typhoid, typhus, scarlet fever, yellow fever, pyemia, ulcerative endocarditis, acute yellow atrophy of the liver, Weil's disease, snake venom, antimony, arsenic, chloral hydrate, chloroform, ether, copper, mercury, phosphorus, and potassium chlorate."—(From Butler's *Diagnostics of Internal Medicine.*)

7. *Ascites is characterized by:* Enlargement of the abdomen, most marked in the flanks when the patient is lying on his back, and in the hypogastrium, when he is standing up; there are dilated superficial veins on the abdomen, and the skin is tense; the umbilicus is prominent; there are fluctuation and vibration on palpation; dullness is found on percussion over the fluid, while the center of the abdomen is resonant.

8. ARTERIOSCLEROSIS. *Symptoms:* "Increased tension in the pulse, causing a hardness, often feeling like 'pipestems.' Great hypertrophy of the cardiac muscle ensues. The coronary arteries may be involved, leading to fibroid degeneration, fatty degeneration, and the symptoms of angina pectoris, absence of compensation, dyspnea, scanty urine, and other symptoms. The cerebral arteries may be involved, and hence apoplexy is common. The kidneys may next suffer, giving rise to interstitial nephritis or contracted kidney." *Dangers:* Cardiac, renal or cerebral troubles. *Management:* "Seek diligently for any predisposing cause. Alcohol in any form should be absolutely interdicted. Attacks of gout and rheumatism should be prevented as far as possible by the restriction of animal foods, tea, and coffee. In these cases a vegetable diet is best. If due to heart disease, kidney disease, or syphilis, each will require its special line of treatment. The kidneys may be kept active by diuretics. At the same time the skin should be kept active by proper amount of exercise, hot baths, and thorough massage."—(Gould & Pyle's *Pocket Cyclopedia.*)

9. The early manifestations of pulmonary tuberculosis are: (1) *Physical signs:* Deficient chest expansion, the phthisical chest, slight dullness or impaired resonance over one apex, fine moist râles at end of inspiration, expiration prolonged or high pitched, breathing interrupted. (2) *Symptoms:* General weakness, lassitude, dyspnea on exertion, pallor, anorexia, loss of weight, slight fever, and night sweats, hemoptysis.

10. LAVAGE is said to be *indicated* in: Gastric dilatation and chronic gastritis. It is *contraindicated* in: "Marked prostration, continued fevers, or cachectic states; broken compensation of heart lesions; advanced fibrous or fatty degenerations of the heart, and angina pectoris; thoracic aneurysm and advanced general arteriosclerosis; last stages of pulmonary tuberculosis, emphysema, bronchitis, and recent hemoptysis; gastric ulcer with recent hematemesis or tarry stools; recent intracranial, renal, vesical, or rectal hemorrhages; and pregnancy and old age."—(Butler's *Diagnostics of Internal Medicine.*)

11. *Tetanus* is a condition of persistent tonic spasm of voluntary muscles; also a disease due to a specific bacillus. *Tetany* is a bilateral, tonic spasm of the extremities.

12. ENLARGED LYMPHATIC GLANDS. (*a*) *Temporary,* in: Diphtheria, tonsillitis, scarlet fever, measles, erysipelas, variola, suppurative ear disease, gonorrhea, chancroid. (*b*) *Persistent,* in: Leukemia, Hodgkin's disease, tuberculosis, syphilis, filaria, malignant disease.

OBSTETRICS, GYNECOLOGY, AND PEDIATRICS.

2. INEVITABLE ABORTION. (*a*) *Diagnosis:* Hemorrhage profuse and continuous, clotted and dark colored; pain cramp-like and severe; cervical canal dilated; uterus soft and enlarged, and the angle between the upper and lower uterine segments is effaced; the discharge consists of dark blood, clots, and portions of ovum; signs of pregnancy present, except amenorrhea.

(*b*) *Management:* "Two methods of treatment have been advised for these cases. The first is *the expectant plan:* Place the patient in bed, and if the bleeding is profuse, insert a tampon of iodoform gauze (one yard) well up against the cervix. If this fails to control the hemorrhage, reinforce it by another yard or two of gauze and a perineal pad and binder. Small doses (3½) of the fluid extract of ergot should now be given every two or three hours. At the end of from eight to twelve hours remove the tampon, when the ovum may be found extruded from the cervix; if not, a vaginal douche of mercuric chloride (1:4000) must be given, and another tampon introduced. If, upon the removal of this second tampon at the end of ten or twelve hours, the ovum is not discharged, then more vigorous methods to secure its expulsion must be adopted. *Active plan:* The physician's hands and instruments are sterilized; the patient is etherized and placed on an appropriate table; the genitalia are thoroughly cleansed and a vaginal douche of mercuric chloride (1:4000) is given; the anterior lip of the cervix is brought down to the vulvar orifice; the cervix is dilated if necessary; the placental forceps is introduced into the uterus, and as much as possible of the ovum is removed; the uterus is thoroughly curetted, and an intrauterine douche of sterile water is given. A light tampon of iodoform gauze is placed in the vagina; the patient is then returned to bed. A strip of gauze may be placed in the uterus in cases of sharp retroflexion, to secure free drainage, and occasionally an intrauterine tampon will be necessary when the uterus refuses to contract and hemorrhage persists after the use of the curette."—(Gould & Pyle's *Pocket Cyclopedia.*)

3. (*a*) *Hydatidiform mole* is a product of conception which has undergone degeneration, and in which the chorionic villi have proliferated so as to produce a mass of cysts somewhat resembling a cluster of grapes. (*b*) *Placenta succenturiata* is a subsidiary placenta, occasionally found, in addition to the ordinary placenta. (*c*) *Caput succedaneum* is a tumor formed during labor upon the presenting part of the fetus; it is due to the absence of pressure at that part. (*d*) *Vernix caseosa* is a greasy substance made up of sebum and desquamated epithelium; it is found on the skin of the fetus at birth. (*e*) *Melena* is the discharge of feces colored black by blood which has undergone changes in the stomach or intestines.

4. For the management of the third stage of labor, see any text-book on obstetrics.

5. (*a*) *Sapremia* is treated: Removal of the decompos-

ing matter by finger, curette, or douche; drainage and asepticizing the affected area; purgatives and diuretics are given; also diaphoretics and stimulants; saline by hypodermoclysis or infusion; food must be fluid concentrated, and nourishing; tonics are indicated; symptoms are treated as they arise. (*b*) *Septic endometritis* is treated: Disinfection of the genital canal, as far as possible; sterile water, saline solution, antiseptic fluids, and curette are all useful; tamponade may be advisable; general treatment as in sapremia.

6. All tears should be repaired as soon as possible (unless there are contraindications). A primary operation is best, because the edges are fresh and can be approximated; little (if any more) anesthetic is wanted; the woman has to lie in bed, and therefore only one absence from household work is requisite; infection is less likely. In any case, operation may prevent rectocele, cystocele, prolapse of uterus, and general weakness, malaise, and disability. For technique, see any text-book on obstetrics or gynecology.

7. Cancer of breast. *Early diagnosis:* Is only conjectural without microscopical examination of a piece of the growth; but a hard nodule, generally painless, steadily increasing in size and incorporated with the gland tissue, should lead one to suspect cancer. Later on the skin is dimpled and may ulcerate, the nipple may be retracted, pain is present, and the breast cannot be freely moved. *Indications for operation:* As soon as diagnosed, and the earlier and more thorough the better.

8. (*a*) For technique of radical operation, see any text-book on surgery. (b) The case is considered "cured" if there is no return within three years of the operation.

9. Pertussis. (*a*) *Diagnosis:* Paroxysms of short, spasmodic coughs followed by a long-drawn inspiration and a "whoop"; the paroxysm may cause puffiness of the face and end in vomiting; the eyes are suffused. (*b*) *Complications:* Convulsions, vomiting, bronchopneumonia, collapse of lung, emphysema, nasal or conjunctival hemorrhage, cancrum oris, paralysis of various kinds. (*c*) *Prognosis:* Guardedly favorable; when complications are present the prognosis is more grave; the character of the epidemic, the age of the child, the care it receives, the number and severity of the paroxysms are all factors to be noticed. (*d*) *Prophylaxis:* Isolation of patient, disinfection of all articles used by him, quarantine while the cough lasts.

10. *Rheumatic manifestations* in children: Fever, sour perspiration, scanty, high-colored urine, arthritis, cardiac lesions with murmur (soft, systolic), accentuation of second heart sound, anemia, night terrors, chorea, quickened pulse, tonsillitis, pericarditis, pleurisy, pneumonia. (*b*) *Treatment:* Rest in bed between flannels and blankets, milk diet; swollen joints should be wrapped in wool; calomel, sodium salicylate, "alkaline treatment" are the main indications.

SURGERY.

1. *Hypertrophy* is said to be *physiological* when it occurs as a phase of the normal life history of the body (such as enlargement of uterus during pregnancy, enlargement of female breast at puberty, and in connection with pregnancy and lactation). All other hypertrophies are *pathological*. *Atrophy* is said to be *physiological* when it occurs as a phase of the normal life history of the body (such as involution of the uterus after parturition; atrophy of the thymus in childhood). All other atrophies are *pathological*.

2. By *infection* is meant the invasion of the living tissues by bacteria, in such a manner as to produce local or general disease. *Chief sources of infection:* Dust, polluted food or water; wounds of all sorts; unclean implements, such as knives, spoons, cups, dental or surgical instruments; fomites; urine, feces, sputum; clothes, dressings; discharges.

3. The *chief complications of gonorrhea* may be: Cystitis, epididymitis, prostatis, vesiculitis, periurethritis, bubo, retention of urine, stricture, gonorrheal rheumatism, and arthritis.

In the *female:* Cystitis, labial abscess, vaginitis, endometritis, salpingitis, ovaritis, peritonitis, and sterility.

4. *Asepsis* is the absence of infection. *Antisepsis* is destruction or arrest of growth of infective germs. *Disinfectant* is an agent which restrains infectious diseases by destroying or removing their specific poisons. *Sterile* means having no living microorganisms. *Deodoronts* are substances which destroy the odorous products of putrefaction.

5.

FRACTURE.	DISLOCATION.
1. Crepitus may be present.	1. Crepitus never present.
2. Preternatural mobility.	2. Rigidity rather than mobility.
3. Easily reduced—but	3. Difficult to reduce—but
4. Deformity more liable to recur after reduction.	4. Deformity less liable to recur after reduction.
5. The head of the bone is in its proper place.	5. The head of the bone is not in its proper place.
6. The socket containing the head of the bone is not empty.	6. The socket which should contain the head of the bone is empty.
7. When rotated the bone does not move as one piece.	7. When rotated the bone moves as one piece.

6. *Pott's fracture* is a fracture of the lower end of the fibula, with outward displacement of the ankle. *Dressing:* After reducing the displacement by extension and manipulation, the limb should be placed in a fracture-box provided with a soft pillow, the foot should be secured to the footboard, and a pad of oakum or cotton should be placed under the tendo Achillis; before bringing up the sides of the box and securing them, two firm compresses of lint or oakum should be placed in contact with the leg and foot, one just above the inner malleolus, the other just below the outer malleolus. The sides of the box are next brought up and secured, and by the pressure of these compresses the foot is brought into an inverted position and the deformity is corrected. The after-dressing of this fracture consists in letting down the sides of the box, and in inspecting the parts to see that the foot is kept in the proper position, and care should be taken that undue pressure is not made upon the skin by the compresses, which might result in ulceration; this may be avoided by sponging the skin with alcohol and changing the positions of the compresses slightly at each dressing. At the expiration of ten days the fracture-box and compresses may be removed and the limb put up in a plaster-of-Paris dressing, including the foot and leg, up to the knee. The patient may then be allowed to go about on crutches, and at the end of five weeks all dressings may be dispensed with." —(Wharton's *Minor Surgery.*)

7. After clean abdominal section, infection may be suspected: If the body temperature is high, if there are chills, exhaustion, marked leucocytosis, night sweats, emaciation.

8. Empyema. *Symptoms:* Fever, sweats, chill, diminished breath sounds and vocal fremitus, impaired mobility of chest, dullness on affected side, heart displaced to opposite side, leucocytosis. *Diagnosis* is made by respiration, showing the fluid to be pus. *Treatment:* Aspiration, drainage, irrigation, resection of ribs (Estlander's operation), or resection of chest wall (Schede's operation).

PATHOLOGY.

1. The *varieties of degeneration* are: Fatty, amyloid, mucoid, hyaline, cheesy or caseous, colloid, hydropic, and cloudy swelling. Tubercle, in chronic cases of tuberculosis, undergoes cheesy or caseous degeneration.

2. See above, Surgery, number 2. *Suppuration* is necrosis and liquefaction of living tissues; it is bacterial in origin, and usually begins as inflammation.

3. Acute endocarditis. *Etiology:* Microorganisms (chiefly *Staphylococcus pyogenes aureus, Streptococcus pyogenes, Diplococcus pneumoniæ,* gonococcus, and others); acute articular rheumatism, pneumonia, scarlet fever, puerperal sepsis, nephritis, etc., are said to be etiological factors. *Pathology:* The valves (mitral, aortic, and pulmonary), and endocardium of ventricles and left auricle are chiefly involved. The valves are affected on a line very near to the free edge; the chordæ tendineæ also suffer, and the endocardium of the left ventricle, near the septum. Opacity, roughness, nodular elevations, fibrous deposit, ulceration have all been observed. *Results:* Calcification, destruction of chordæ tendineæ or valve, myocarditis, pericarditis, embolism, infarcts or metastatic abscesses in spleen, brain, or kidneys.

4. *Endarteritis* is inflammation of the inner coat of an artery. *Endarteritis obliterans* is endarteritis in which the lumen of the affected vessel is almost obliterated. *Ultimate results to tissues:* The blood supply is cut off; in the brain, cerebral softening and paralysis result; neuralgia may occur; hemorrhage is prevented.

5. *Granulation tissue* is embryonic tissue consisting of loops of new formed capillaries covered by round cells, and sometimes also by giant cells. It is formed as a result of inflammation during the repair of wounds when apposition is not perfect.

6. In *leukemia*, the *blood* is light in color, specific gravity is lowered, coagulation is slow, the white corpuscles are much increased in number (there may be from 150,000 to 500,000 per c. mm., or even more); myelocytes are present in large numbers in the splenomedullary type; red cells may be moderately diminished, and some may be nucleated. The *spleen* and *lymphatic glands* are enlarged.

BACTERIOLOGY.

1. *Obligate aerobe* is a term applied to such bacteria as cannot exist without oxygen. *Facultative anaërobe* is a term applied to such bacteria as thrive better without oxygen, but still can manage to exist in oxygen. *Germicides* are agents which destroy bacteria and their germs. *Disinfectants* are agents which restrain infectious diseases by destroying or removing their specific poisons. *Antiseptics* are agents which destroy infection. *Aseptic* means absence of infection, or freedom from germs.

2. The tubercle bacillus is rod shaped, is from 1½ to 3½ mikrons in length, and about one-third to one half a mikron in breadth, is a strict parasite, is not motile, and has no flagella. It is slightly curved, does not form spores, is not liquefying, and nonchromogenic, is aërobic; it resists acids; it grows well on blood serum; stains well by Ehrlich's, Ziehl-Nielsen's, or Gabbett's method; it is Gram-positive.

3. *A motile* pathogenic microorganism: *Bacillus typhosus.* The power of motion is due to flagella. The most common pyogenic microorganisms: *Staphylococcus pyogenes aureus, Staphylococcus pyogenes albus, Staphylococcus pyogenes citreus,* and *Streptococcus pyogenes* A pathogenic diplococcus: The gonococcus.

NEUROLOGY.

1. *Neurasthenia* is a condition in which nervous energy is diminished, and sensitiveness to external impressions is increased. *Psychasthenia* is mental fatigue. A *tic* is a spasmodic and involuntary contraction of the (facial) muscles; also a neurosis. In *tonic* spasms, the contractions are continuous. In *clonic* spasms, the contractions are intermittent.

2. *Symptoms of acute anterior poliomyelitis:* Some fever, chills, and convulsions may precede the paralysis, or the onset may be sudden; certain groups of muscles (generally in the extremities) are paralyzed; hemiplegia is rare; the reflexes are generally lost; the paralysis is irregular in its distribution, and tends to ameliorate, but the recovery is only partial; the affected muscles waste, and the limb is cold and livid.

3. Locomotor Ataxia. *Symptoms:* Loss of coordination; characteristic and unsteady gait; tendency to stagger when standing up with feet together and eyes closed; sharp and paroxysmal pain, called *crises;* girdle sensation; loss of knee-jerk and other reflexes; Argyll-Robertson pupil. The *diagnostic features* are: A slow onset; the loss of the patellar reflexes; Argyll-Robertson pupil; lightning pains; incoordination. *Treatment:* Rest, tonics (strychnine, arsenic, iron, and phosphorus); easily digestible food; hydrotherapy; massage; electricity; reeducation of muscles; avoidance of all excesses, cautery; anodynes.

HYGIENE.

1. *Dangers incident to drinking spring and well water:* Surface water, filth, sewage, and, indeed, anything *may be* conducted into these waters. Hence, the possibility of disease being caused by drinking this water. The wells and springs should be at a distance from dwelling houses, especially from outhouses, privies, etc.; they should be well protected and covered, so that no extraneous matter can enter them. All shallow wells should be protected with good coping stones and good masonry for several feet below the surface.

2. Hygienic precautions to be taken in treating a case of tuberculosis: "The patient's quarters should be free from dust, and admit of spending many hours daily in the open air in all weathers, properly sheltered, and, if very ill, lying wrapped in a hammock or reclining chair. His bedroom should be well aired at night, draughts being avoided. The room should be uncarpeted and free from hangings. It should be often cleaned and periodically disinfected. All sputum should be collected in paper spit-cups, which should be burned daily. Smoking should be forbidden. Harm is done by any exercise which results in fatigue, and while fever exists it should not be attempted at all. Patients should be taught the necessity of practising lung gymnastics and breathing only through the nose, which should be kept clear and free from occlusion by secretions, or an hypertrophied catarrhal mucosa. . . . The clothing should be woolen, but not too heavy, or sweating is increased; and a flannel nightgown and loosely knit leggings should be worn at night in cool weather. The skin should be cleansed by daily sponge-baths of lukewarm alcohol and water."—(Thompson's *Practical Medicine.*)

3. *Diseases of animals communicable to man:* Glanders, anthrax, tuberculosis, rabies, aphtha, tapeworm and other intestinal parasites, ringworm, echinococcus, diphtheria.

Chief impurities of air in large cities: Mineral matters, as silica, calcium, iron; coal dust; spores of moulds and bacteria; organic matter; ammonia; fibers of cotton, wool, or silk; dust and fibers from industrial processes; gases, products of combustion.

HISTOLOGY.

1. A *nerve* consists of a bundle of fibers bound together by a sheath called the *epineurium;* it contains blood-vessels, lymphatics, connective tissue cells; each nerve bundle is surrounded also by a sheath called the *perineurium. Medullated fibers* consist of a neurilemma, medullary sheath, and axis cylinder. *Nonmedullated fibers* have an axis cylinder, but no sheath. *Nerve cells* have cell-body, nucleus, and one or more processes (axis cylinders and dendrites).

2. *Peyer's patches* are clumps of solitary glands covered with mucous membrane and surrounded by crypts of Lieberkühn. Each of these solitary glands is a lymph nodule consisting of retiform tissue, lymph corpuscles, and capillaries. They are situated in the mucous and submucous tissue of the small intestine, chiefly the ileum.

Arteries consist of three *coats:* (1) *Tunica intima,* consisting of fenestrated membrane of Henle, and a fine line of white fibrous tissue; (2) *Tunica media,* consisting of elastic fibers and involuntary muscles; (3) *Tunica adventitia,* consisting of white fibrous tissue and a few elastic fibers. The middle coat is the thickest.

LARYNGOLOGY.

1. *The symptoms of adenoids in children* are: Mouth-breathing; snoring; open-mouth; a vacant, dull expression of the face; modification of the voice. *Effects:* Otitis, coryza, mental deficiency, stunted growth, and various neuroses.

2. *Aphonia* is loss of voice, caused by: Laryngitis, edema or tumor of larynx, improper use of the voice, retropharyngeal abscess, paralysis, fixation of the vocal cords, by cicatricial contractions, ulceration of the vocal cords, foreign bodies in the larynx, and hysteria.

3. The essential cause of diphtheria is the Klebs-Loeffler bacillus. The essential cause of true croup is either the Klebs-Loeffler bacillus, or the *Streptococcus pyogenes.* In *diphtheria* the onset is more gradual; the temperature rises to about 101° to 103° F.; the tonsils are not much enlarged; there is an exudate of a thick grayish membrane which is very adherent, is removed only with difficulty, and leaves a bleeding surface; this membrane soon re-forms, and may be found on the fauces and pharynx as well as on the tonsil; in the exudate the Klebs-Loeffler bacilli may be found. In *follicular tonsillitis* the onset is more sudden; the temperature may be a little higher than that of diphtheria; there is no membrane, but the tonsils are red and swollen, and in the crypts are seen white cheesy spots or plugs, which consist of broken-down epithelium, and are easily brushed away; Klebs-Loeffler bacilli are never found.

RHINOLOGY.

1. *Local:* Trauma, caries of nasal bones, ulceration, new growths. *General:* Purpura hæmorrhagica, hemophilia, scurvy, pernicious anemia.

2. Mucosa of nasal cavity, especially of inferior turbinated bones. *Symptoms:* Increased secretion, obstruction, sneezing, loss of resonance of voice, impaired olfaction, bad breath. *Treatment:* Cleansing alkaline spray, astringent spray, cauterization, incision, or turbinectomy.

Chronic atrophic catarrh. *Symptoms:* Blocking of the nose with thick, offensive crusts; nasal fossæ dilated; anosmia. *Treatment:* A warm, alkaline, cleansing douche; the crusts must be removed; tampons with ichthyol, followed by an oil spray, have been recommended. It is usually called ozena, on account of the offensive fetid smell.

OPHTHALMOLOGY.

1. *Ptosis* is a drooping of the upper eyelid. *Strabismus* is a perceptible deviation of one of the eyes from the proper direction. *Diplopia* is the condition in which an object appears double. *Myopia* is a condition in which the parallel rays are focused in front of the retina. *Hypermetropia* is a condition in which the parallel rays are focused behind the retina. *Presbyopia* is a physiological change in which there is progressive loss of the accommodative power of the eye as age advances. *Chalazion* is a tumor in the eyelid, due to obstruction of the duct in a Meibomian gland.

2. *Etiology:* Irritation, a foreign body, cold, exposure to

strong light or heat, eyestrain. *Symptoms:* Hyperemia, lacrymation, epiphora, discharge, photophobia, sensation of sand in the eye. *Treatment:* Remove cause; use astringent and antiseptic washes; anoint the lids with vaseline. When it becomes contagious, its common name is "pink eye."

3. OPHTHALMIA NEONATORUM. *Causes:* The gonococcus or some other pyogenic microorganism; the secretions of the mother contain the infecting agent, and transmission may occur directly during parturition, or indirectly by the fingers of physician or nurse, cloths, instruments, etc. *Symptoms:* Swollen eyelids, with copious purulent discharge; ulceration of the cornea may ensue. *Prophylaxis:* Whenever there is the possibility of infection, or in every case, wash the eyelids of the newborn child with clean warm water, and drop on the cornea of each eye one drop of a 1 per cent. solution of nitrate of silver, immediately after birth. *Treatment:* Wash the eyes carefully every half hour with a saturated solution of boric acid; pus must not be allowed to accumulate. Two drops of a 2 per cent. solution of nitrate of silver must also be dropped on to the cornea every night and morning. The eyes must be covered with a light, cold, wet compress. The patient must be isolated, and all cloths and compresses used must be burnt.

OTOLOGY.

1. (1) Insects, by warm water or chloroform oil; (2) by syringing; (3) wax may be removed by disintegrating it with hydrogen dioxide, followed by warm water irrigation.

2. *Etiology:* Infection from nasopharynx or ear, exanthemata, grippe. *Symptoms:* Tenderness, pain, swelling and redness over the mastoid; bulging of the superior and posterior parts of the auditory canal; temperature variable, from normal up to about 104° F. *Treatment:* Hot water, or cold water, or ice; leeches, purgatives; light diet; incision or mastoid operation. *Three common and serious results:* Meningitis, sinus phlebitis, abscess of the brain.

BULLETIN OF APPROACHING EXAMINATION.†

STATE	NAME AND ADDRESS OF SECRETARY	PLACE AND DATE OF NEXT EXAMINATION	
Alabama*	W. H. Sanders, Montgomery	Montgomery	Jan. —
Arizona*	Ancil Martin, Phoenix	Phœnix	Jan. 3
Arkansas*	F. T. Murphy, Brinkley	Little Rock	Nov. 9
California*	Chas. L. Tisdale, 1879 Sutter Street, San Francisco	Los Angeles	Dec. 7

* No reciprocity recognized by these States.

† Applicants should in every case write to the secretary for latest details regarding the examination in any particular State.

Medical Items.

Contagious Diseases, Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, New York City, for the week of October 30, 1909:

	Cases	Deaths
Tuberculosis Pulmonalis	435	147
Diphtheria	262	29
Measles	115	6
Scarlet Fever	145	8
Smallpox	—	1
Varicella	56	—
Typhoid Fever	83	21
Whooping Cough	36	2
Cerebrospinal Meningitis	6	6
Malarial Fever	—	—
Totals	1,138	220

Modification of Neuromuscular Electric Excitability Caused by the X-Rays.—Diego Malcagni has found that the neuromuscular mechanisms show some changes in their excitability after the use of the *x*- rays. He sums up his observations thus: The effects occur immediately after the *x*-ray application; the electric excitability is diminished, contractions are weaker, and the secondary contraction is less. This condition persists for about fifteen minutes and then gradually diminishes. This action on the peripheral nervous system is not cumulative. It varies in different parts of the organism; at some applications the effect is only transitory, while at others it is more persistent. There is no regularity about this effect.—*Giornale di Elettricita Medica.*

Health Reports.—The following cases of and deaths from smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, Public Health and Marine-Hospital Service, during the week ended October 29, 1909:

DIABETIC COMA: IS IT DUE TO ACIDOSIS?*

By HENRY S. STARK, A.M., M.D.,

NEW YORK.

JUDGED from the standpoint of recent physiological data, I believe the time is ripe to repudiate the prevailing theory that diabetic coma is due solely to an acidosis, and it is the purpose of the writer to prove that our views of the causation of this terminal phenomenon of diabetes are unsuited to present day conditions, and that they must be modernized to suit current conception. While I am aware that in making this radical departure from a tradition that has been embodied in successive texts without having been put to proof, I shall draw out much criticism, still I believe that we have allowed ourselves to fall into the strange error of attributing this phenomenon to the presence in the urine of fugitive acids whose pathological and clinical significance when first discovered must have been merely conjectural and whose properties even to this day lack experimental and physiological confirmation. Even the postulate upon which this theory was originally based, namely, that the acetone bodies were derived from proteins, is scouted to-day.

In speaking of diabetic coma, if such a distinct entity exists at all, reference is made solely to the coma described by Kussmaul and known by his name. It is the true, or specific, or dyspneic diabetic coma. It has never been possible to ascribe to it any definite lesion of the viscera, nevertheless it may be assumed that it depends essentially on the diabetic dyscrasia. There are, however, several accidental or pseudo-types of coma, not fundamentally diabetic, but are, correctly speaking, the fatal issue of an intercurrent affection. Such a pseudo-type is the cardiac coma due to collapse from a myocarditis, another is, in effect, a syncope following in the wake of a complicating nephritis. Inasmuch as the question of acidosis has no bearing on the pseudo-types, they will be considered as irrelevant to this paper.

Death from true diabetic coma does not occur as frequently as is commonly believed. Counting only well-defined cases, to the exclusion of the pseudo varieties, diabetes ends in coma in about 40 per cent. of all cases. The clinical differentiation between the true and false types of coma is often beset with difficulty, especially so when the urinary evidences are wanting or contradictory.

As a matter of history, the acidosis theory came into existence as a natural evolution of a mass of undeveloped chemical data, among which chemical formulæ and equations were juggled in a manner as to make it appear that an abnormal chemism of the members of the fatty acid series was responsible for the coma. Every known chemical process was invoked, with a view of constructing a theory of origin or of isolating a substance which could be clothed with the distinction of being the causal element of the coma. But even to this day it has been found impossible to produce a chemical agent that exactly fitted the clinical picture or combined all the attributes that resulted in the varied phenomena of coma.

When the discovery was made that a member of the fatty-acid series, namely β-oxybutyric acid was a not infrequent accompaniment of diabetes, this association was at once seized upon to account for the coma, although the physiological factors upon which this excretion depends, were never established. It was looked upon as an anabolic effect and inasmuch as it involved the fatty acids, the offending organ was presumed to be the liver. But whether the terminal coma was due to the behavior of this acid toward ferments, enzymes, or micro-organisms, or depended upon its quantity or quality, was never explained.

It is a physiological fact that during the metabolism of proteins and carbohydrates, as well, a number of clearage products of an acid nature are produced. Is it not as likely that one or other of these is liable to be responsible for coma, as it is claimed for β-oxybutyric acid? For instance, during the pancreatic digestion of proteins, various amino acids are formed which later are excreted in changed form in the urine. These acid-bodies likewise possess the same faculty of uniting with alkali bases and preventing the physiological absorption of carbon dioxide, and, therefore, capable of initiating pathological changes. In their effects on metabolic functions some of the cleavage products and the acetone bodies are closely analogous, and at various periods of investigation crotonic, lactic and the mineral acids were held responsible for the coma. The possibility that the amino acids may be the precursors of acetone bodies, is always to be reckoned with.

It has been clinically established that β-oxybutyric acid may be profusely and continuously excreted over long periods by diabetics without serious impairment of health. How is this comparative innocuousness explained? Sixty to 80 grams per day are not unusual. Bainbridge[1] said that "there were many facts which go to show that β-oxybutyric acid is a normal metabolic product." Spitzer[2] claims that in pancreatic diabetes no acidosis can be produced with β-oxybutyric acid. It seems probable that, not only in health, but even in the course of diabetes, this acid can be perfectly metabolized up to a certain point. Von Noorden[3] tells us that "It is not known whether the acetone bodies are really normal intermediate products of fat catabolism."

*Read at the May meeting of the Harlem Medical Society.

The question seems to hinge upon the toxicity of this acid. If it could be pathologically established that the acetone bodies possess definite toxic qualities, the nature of the coma would be explained. But experimental research upon man and animals to establish the toxicity of these acids have been signally fruitless. True there have been recorded, deaths in animals after intravenous injections of β-oxybutyric acid, but in these isolated instances objection could be reasonably raised as to their final value on the following score: Firstly, that the fatal phenomenon observed was not coma; secondly, that death was not caused by diminished blood alkalescence; and thirdly, that death was due to accidental causes other than those due to the acetone bodies. Further the value of animal experimentation can be overruled on the ground that in almost every instance the acid in the experiment was administered in one or two maximal doses, whereas in human diabetes, the acid, if at all toxic, is insidious and cumulative in its toxic effects. Coma as a fatal issue in dumb animals is often impossible of differentiation, while there are no post-mortem findings upon which to establish that death was due to an hyperacidosis.

As far as the toxicity of this acid is concerned, there are a number of elemental facts which must be reconciled before such a claim can be validated. As stated before, large quantities can be excreted for years without physiological disturbances ensuing. A daily excretion for years of 20 to 30 grams is not unusual. Külz[4] found as much as 100 to 200 grams in 24 hours. Von Noorden[5] often found 60 to 80 grams per day and states he knew of many diabetics who excreted 50 to 60 grams daily for six years and nevertheless enjoyed good health. Naunyn[6] refers to a case of diabetes in which there was for years an excretion of 100 grams of β-oxybutyric acid. Ewing[7] makes the statement that "When 40 grams of oxybutyric acid may be excreted in one day in a case of syringomelia, without symptoms of intoxication, it is difficult to maintain that this acid exerts any immediate toxic action."

According to different observers and to the same observers on different occasions, the quantity of acid excreted, immediately preceding coma, fluctuates within wide limits. This amount ranges on the first day of coma from eight grams to several hundreds. It is difficult under such circumstances to draw practical deductions as to the relative toxicity of the acid, or amount that may be considered decisive of coma. The gross disparity in amount of acid output at the onset of coma, together with the enormous amounts excreted for long periods without visable impairment of health, must be interpreted to mean that the acidosis theory alone cannot be sustained as proven for diabetes.

What has so far been established is that these pathological acids exert their injurious effects by virtue of their acidity and not by virtue of their toxicity. In other words, the acetone bodies may prove detrimental to health by reason of their affinity for the alkali bases of the blood and their indirect action of inhibiting the absorption of carbon dioxide. But I think it must be admitted that intrinsically, they are nontoxic. It is anomalous that an agency supposedly poisonous, which is produced for years in diseased organisms, should give rise suddenly to a fatal crisis without demonstrable lesions and without being preceded by marked organic prodromes, save a nausea or dyspnea of short duration. A number of times I have seen diabetics in fairly good health, who a few hours later were in the throes of a fatal coma, without apparent exciting cause.

Such an unheralded onset and fatal termination of a systemic intoxication it is difficult to duplicate in the whole gamut of chronic constitutional poisonings, whether by organic acids, metallic poisons, tobacco, alcohol, urea, gases, ptomaines, or toxins. As a species of intoxicant, β-oxybutyric acid, in this respect, is without a prototype. If we argue that coma was due to acetonemia, on the mere finding of pathological acids in the urine of diabetics, one might claim with equal propriety that coma was caused by other pathological constituents of the urine, such as urea, ammonia, ammonium salts, glucose itself, or one of the urinary products of intestinal putrefaction, or of hepatic insufficiency. It is easy to conceive how such products may be excreted in quantities large enough to provoke a state of coma. And how in such an event the clinical picture would be radically no different from the coma of supposed acid origin. There are no characteristic features by which diabetic coma can be differentiated objectively, save by the presence of urinary glucose, nor can the group of symptoms be accounted for solely on the basis of an acid-intoxication. Lépine[8] says that acidosis does not explain the pulse and dyspnea of diabetic coma, but believes a toxin would fit the case exactly.

In a previous communication[9] I made the statement that the theory of origin which more completely harmonizes with the clinical picture and the physiological data, is one based on the recognition of an enterogenous toxin, developed in the small intestines, through the vitalizing influence of either several species of bacteria or of one specific organism upon some one ingredient of the digestive secretions, probably of the pancreas. Such a toxin would find its way into the general circulation, thence to the respiratory center. The probability of such a toxin is enhanced by the fact that gastrointestinal phenomena often precede the onset of coma and that coma is often a casualty of surgical operations upon diabetics. Up to date such a substance has not been isolated in pure state, but it would seem that the discovery of certain toxins resulting from intestinal putrefaction of proteins through the intermediary of bacterial life, namely, the indol group, produced by the *bacillus coli*, suggests that a counterpart may result due to the disordered metabolism of carbohydrates, in other words arising from the decomposition of sugar and starches. This would mean that the toxin of coma is a decomposition product due to intestinal putrefactive bacteria, not necessarily giving rise to abnormal constituents in the urine, and not always sufficiently virulent to cause marked constitutional poisoning. The degree of coma would correspond to the intensity of the intoxication, varying from a transient unconsciousness to a profound somnolence. It is this property of the toxic element, namely its degree of virulence, which serves to explain those recoveries from diabetic coma which it has been erroneously claimed were due to the alkali therapy. A more plausible interpretation of these cures is found in the capacity of the economy to adjust itself to a moderate toxicosis, but eventually to succumb to an overflooding of it.

In this connection it is worthy of comment that most investigations of the origin of this coma have been made along chemical lines almost to the entire

exclusion of biological possibilities, and yet, taking into consideration the sequence of events and their fatal termination, the inference is almost forced upon us that the toxic agency is biological in nature, in the genesis of which an enzyme, a ferment or bacterial life, is the activating medium. Looking at the matter, clinically, the symptoms associated with coma, together with their mode of onset, cannot be acounted for on the basis of an acid-intoxication, for the obvious reason that diabetic acidosis does not set up a lesion of any organ. Pathology has not been able to create, so to speak, an acidosis entity in diabetes. Efforts to establish a lesion for certain other clinical types of acidosis have been more successful. Thus a fatty degeneration of the liver has been proven in connection with pernicious vomiting of pregnancy, in cyclic vomiting of children, in delayed poisoning following anesthetics, in eclampsia, and in acute yellow atrophy. But as far as diabetic acidosis is concerned, pathological anatomy has been a closed book, except that we sometimes meet with a nephritis toward the end of the disease which bears no relation to the acidosis.

From the viewpoint of physiology the theory of acidosis is overshadowed by the essential fact that a free acid cannot exist in the blood. As Osler says, "in any event an acid reaction of the blood can be only a terminal phenomenon."[10] The very term "acidosis" is ambiguous and a misnomer. Strictly speaking, what is meant is a decreased alkalinity of the blood. In the case of diabetics, nature provides an efficient factor of safety against such a contingency as an over-production of abnormal acids and consequently a defense against a subalkalinity. Firstly, in the greatly increased excretion of ammonia which compensates for the acids, and, secondly, in the alkali bases of the blood which neutralizes them.

An acidosis, however severe, cannot be regarded as an anatomical entity. It is, in reality, one phase of a disturbed metabolism accompanied by certain cleavage products of an acid nature, which experience has shown appear to have no toxic properties in man or animals. An acidosis does not develop into an acid intoxication without being reinforced by a toxic agent. Under such circumstances alone these acid bodies or other abnormal cleavage products may culminate in diseased states. In the present state of our knowledge of the pathogenesis of diabetes we cannot differentiate diabetic acidosis from that found in health on a starch-free diet. In point of fact it is argued that the former is but an expression of sugar-starvation.

Now, if acidosis means an increase in the economy of substances endowed with acid properties, the organs, tissues, cells, and the normal acid secretions ought all give evidence confirming this acid-saturation, while the latter would manifest itself in a characteristic clinical picture. We would expect to find respiratory disturbances such as dyspnea and cyanosis, due to the following changes in the blood, the abstraction by the acid bodies of the fixed alkalis, the decrease of the carbon dioxide content, and the deficiency of oxygen. But clinical experience has abundantly shown that this symptom-complex does not always follow in the wake of an acidosis. Often a severe acidosis in diabetes does not even cause appreciable metabolic disturbances, and save for the urinary findings would actually escape detection. We have, thus, no well-defined subjective symptoms pathognomonic of an acidosis save when the disease has nearly run its course.

In order to determine logically and scientifically what influence acidosis has in the causation of coma, it is incumbent upon ourselves to determine quantitatively the alkali index of the blood. This would serve to define the point where physiological alkalinity ends and pathological alkalinity begins. But this is not an easy matter. The methods available for the determination of blood alkalinity are conflicting in their results, too technical to be clinically useful, and are subject to disturbing physiological influences, such as sex, diet, period of digestion, physical eruditions, and state of the functions. The degree of alkalinity is not a fixed quantity, but varies in different subjects and in the same subject at different times. There are daily oscillations even in the healthy state. The term alkalinity is consequently a relative and empirical one, employed without reference to a constant or definite standard. In the same way the term acidosis is used relatively and without any consideration of the degree, extent, or distribution of the acid radicals. Experience has shown that a certain degree of subalkalinity is physiological, and that a marked degree occurs in a number of diseases, such as severe anemias, certain toxemias, some of the infectious diseases, and malignant disease. Yet in spite of the occurrence of a subalkalinity in these diseases, the conception of a typical coma as a terminal incident in connection therewith has received scant attention. Investigations to determine the blood alkalescence of diabetics in coma or to determine the toxicity of diabetic blood during coma, would carry great weight, but unfortunately such studies are so scarce that definite deductions relative to the pathologic significance of a subalkalinity are not permissible. Experimental proof along such lines, if it could be furnished, would be a vindication of the acidosis theory. As long as the degree of acidosis cannot be directly determined, but must be estimated in terms of ammonia, a method which is open to serious objection and encompassed by numerous difficulties, we are not in a position to judge what effect the acid bodies have on the vital functions. Then again, it is to be borne in mind that it is not the urinary acetone bodies which would induce disturbances in health, but rather the acetone bodies that would be retained in tissue and cell. What relation the excreted acid bodies bear to the retained acid bodies is purely conjectural. Were we assured of this ratio, the question how far the acidosis or the subalkalinity was involved in coma would be past dispute. But here again experimental work has been of little value. Relatively little is known of the quantitative relation that exists between the normal acid and alkaline secretions of the body. There probably does exist an acid equilibrium and an alkaline equilibrium for the economy analogous in its operations to the nitrogen equilibrium, and like the former, too, the latter are subject to deflections from the normal, manifesting themselves clinically. It has been established in health that there exists a constant correlation[11] between the gastric acidity and the urinary acidity, and that in disease this reciprocal relationship announces itself in well-recognized acidity curves. Osler[10] tells us that in hyperacidity of the stomach the urine acidity decreases proportionately with the increase of acidity of the gastric juice. Some time ago, becoming impressed with the idea that if diabetic coma was caused by an acidosis, the latter would disclose itself in an appreciable increase in the quantitative acidity of the normal acid secretions of the body, notably of

the urine and gastric juice, the following experiment designed to establish the merits of this deduction was instituted: the urine and gastric juice of two adult patients who were known to have an acetonuria of long standing and who were dying of diabetic coma, were obtained and submitted to the following tests, the quantitative acidity of the gastric juice and of its free hydrochloric acid, and of the native urine were estimated. The figures showed a slightly increased acidity of both secretions and of free acid, but the increase was not sufficient to warrant the belief that it was attributable to the acidosis. This result was disappointing, for it was but natural to suppose that if acidosis meant anything at all it would signify that the tissues, blood, and cells were so overrun with acids that a vent for this acid tide would be found in the physiological acid secretions of the body, even though a decided drop in the output of the acid elements often precedes the onset of coma.

Opposed to the assumption that the coma is due to acidosis, there is a mass of clinical evidence which it is difficult to contradict. Firstly, a decided acetonuria occurs in the course of numerous diseases of widely different characters, *e.g.* gastrointestinal disorders of childhood (cyclic vomiting), acute yellow atrophy of the liver, eclampsia, pernicious vomiting of pregnancy, intoxications from metals and anesthetics, etc., etc.

Secondly, acidosis may occur in health on a continuous sugar-free diet, also during physiologic starvation, and during inanition from wasting disorders, such as carcinoma and tuberculosis.

Thirdly, adyspneic coma, not unlike true diabetic coma, is met with in other diseases than diabetes, such as measles, scarlet fever, and typhoid fever. Save for the presence of dextrose in the urine, these comas could not be clinically differentiated.

Fourthly, diabetic coma may occur without acidosis, but with a large ammonia excretion. There are quite a number of such cases recorded in literature, and they have an important bearing on the question of the origin of coma.

Fifthly, alkali therapy has been notoriously a failure, either as a prophylactic or as a curative measure. In connection with the claim that alkali therapy has arrested or cured diabetic coma, exception is made on the following score that the coma in question was a type of pseudodiabetic coma, or that the improvement observed to follow the intravenous injection of an alkaline solution was not directly attributable to the alkaline nature of the fluid injected, but rather was due to the very act of injecting a volume of fluid into the circulation. The failure of alkali medication, either to abort or to tide the patient over, an attack, seals the fate of the acidosis theory.

1309 MADISON AVENUE.

THE TREATMENT OF AMEBIC DYSENTERY.*

BY W. E. DEEKS, M.A., M.D.,
CHIEF OF MEDICAL CLINIC ANCON HOSPITAL,
AND
W. F. SHAW, M.D.,
PHYSICIAN ANCON HOSPITAL.

ON the 12th of December, 1908, one of the authors published in the MEDICAL RECORD a preliminary note on the treatment of amebic dysentery as conducted on the Isthmus of Panama. We wish now to present an analysis of 211 cases, some of which were treated by the method therein indicated and the rest by other means generally recommended by the profession.

From January 1, 1905, to July 1, 1909, the charts of 358 patients appeared in the files of the hospital which had been diagnosed as amebic dysentery. From these charts 211 were selected as those characteristic of the affection, the remaining 147 were rejected because no dysenteric symptoms were present while they were in the hospital, though amebæ were found in the stools during the routine examinations which were made.

There is no attempt in this paper to discuss the biological characters of the ameba which is responsible for the well-known and characteristic disease, nor of the pathological changes occasioned thereby, but merely to discuss the best and simplest means of dealing with this at-oft-times formidable affection.

The observations of Musgrave and Clegg that the specific ameba can only be grown in a medium which contains microorganisms is interesting and throws a great deal of light on its pathological processes and the treatment.

Whether there be a pathogenic and a non-pathogenic variety or varieties, with characteristic morphologies, or whether the apparently different morphological characters are due to symbiotic environment and nutrition of a single variety, the writers are not prepared to say, as no special attention has been directed to the differential characters. The presence of large motile amebæ containing red cells with the associated dysenteric symptoms being sufficient to make the diagnosis. One thing, however, is certain and has been repeatedly demonstrated here, that the pathogenic variety can and does remain over long periods of time in the intestinal tract without producing pathological symptoms. But when some intercurrent acute affection, such as tuberculosis or pneumonia, lowers the vitality sufficiently, the dysentric symptoms then manifest themselves and are responsible frequently for the lethal termination which post-mortem examinations demonstrated. We have also seen here a more or less severe attack of amebic dysentery supervene on the injection of some irritating substance like silver nitrate solutions and quinine solutions into the bowel in patients in whom the amebæ had been accidentally discovered in the course of routine examination, and when no dysenteric symptoms previously existed.

The symptoms upon which the diagnosis of amebic dysentery are based here are frequent dysenteric stools with or without tenesmus, a coated furred tongue, more or less irregular fever, prostration, and distress, with the presence of large motile amebæ, blood, pus, epithelium, and mucus in the

*Read before the Canal Zone Medical Society, August, 1909.

stool. In addition, there is abdominal tenderness over the large bowel in some part of its course, but most frequently over the cecum and sigmoid flexure.

Another symptom which is present in almost every case, in a more or less marked degree, is the loss of elasticity of the skin. It is more marked over the abdomen than other parts. It has a peculiar doughy or putty-like feel, and when stretched slowly crawls back to its normal position in a worm-like manner. As a rule, the more marked this condition the graver the affection. This same condition of the skin, however, is found in other severe affections involving the abdominal viscera, as intestinal tuberculosis, severe nephritis and hepatitis, severe typhoid, and very grave diseases associated with inanition, and is therefore not peculiar to, though characteristic of, severe amebic dysentery.

Amebic dysentery is liable to be confounded with severe colitis from any cause, bacillary or secondary to nephritis, liver cirrhosis, or intestinal tuberculosis. Careful examination of the other organs with the presence or not of amebæ in the stools is sufficient to clear up the diagnosis.

The comparative occurrence during the time above mentioned for months and years is as follows, with the percentages of fatal terminations:

	1905	1906	1907	1908	1909
January	1	2	5	5	5
February	1	2	9	1	3
March	0	3	12	4	7
April	2	3	14	1	5
May	0	0	10	1	7
June	1	2	11	3	4
July	1	8	6	3	
August	0	9	5	3	
September	0	6	6	2	
October	1	5	5	0	
November	2	6	3	2	
December	1	9	2	2	
Totals	10	55	88	27	31
Deaths	3	20	26	5	2
Deaths, per cent	30	36	29	18	6.5

The number of cases increased especially during the latter half of 1906 and the first half of 1907, when the maximum admission occurred, decreasing markedly in 1908, but again increasing this year. The number of deaths increase correspondingly but the percentage death rate declined since 1907.

As regards nationalities, the Americans show a high rate of infection and indicates that the ameba flourishes on the Isthmus and is not necessarily introduced by other nationalities, though the Panamans themselves do not show infection in very large numbers, upholding the idea that the native may have a special resistance to the disease. From Jamaica there were 44 cases; Barbados, 43; United States, 34; Guadeloupe, 11; Colombia, 9; France, 9; Spain, 7; Martinique, 9; Panama, 5; Antigua, 5; Grenada, 4; Italy, 2; Canada, 2; England, 2; Venezuela, 2; Sweden, 2; Montserrat, 2; St. Lucia, 2; Hayti, 1; Trinidad, 2; West Indies, 1; St. Kitts, 1; Cuba, 1; St. Thomas, 1; Germany, 1; Fortune Island, 1; Dominica, 1; St. Vincent, 1; India, 1; Mexico, 1; Ireland, 1; Greece, 1; unknown, 2. Total, 211. These are practically in direct ratio to the nationalities here. Of these, 3 French, 1 Italian, 1 English, 2 Canadians, and 5 Americans had previously been in the tropics.

There were 205 males and 6 females (U. S. 3, St. Thomas 1, Jamaica 2). The United States females had never been in the tropics previously; one a school teacher 4 months on the Isthmus, one a housewife 7 months on the Isthmus, the third, time unknown.

Occurrence and deaths during the different decades of life is shown by the following table:

Ages	Cases	Deaths
10–20 years	22	4
20–30 "	87	19
30–40 "	61	18
40–50 "	21	8
50–60 "	12	5
60–70 "	3	0
70–80 "	1	1
Unknown	4	1
	211	56

In the later decades of life the mortality was higher.

Every village on the Isthmus contributed one or more cases, the places of a greater population having a correspondingly larger number of cases, Panama, heading the list, though so few Panamans were admitted, showing again a resistance of the native or a decreased resistance of the foreigner. It also shows that there was no endemic center from which it spread, as there were from Panama, 34 cases; Empire, 19; Ancon, 16; Paraiso, 14; Las Cascadas, 13; Pedro Miguel, 11; Culebra, 12; Gorgona, 10; Balboa, 10; Rio Grande, 8; Tabernilla, 7; Cunette, 6; Bas Obispo, 7; Corozal, 5; Bohio, 5; San Pablo, 5; Gatun, 5; Matachin, 4; Miraflores, 3; Chagres, 2; Colon, 2; Gold Hill, 1; Lirio, 1; Frijoles, 1; Caledonia, 1; Cerro, 1; Mamei, 1; Cucaracha, 1; Tivoli, 1; unknown, 1. The cases occurred in proportion to the population in the various towns.

But 7 cases have a record of second attack among this series, though some of the patients stated that they had had previous dysenteries which, except by presumption, could not be diagnosed as amebic. A number of the charts which were not accepted indicated that the patients complained of a tenderness or slight pain in the abdomen alone, of a slight increase of stools for one or two days, yet in examining cases for a period covering more than four years so few reappear with a typical attack the inference would undoubtedly be true that the attacks are not nearly so frequent as is generally supposed, and that when proper treatment is given recurrences are rare.

Of those who had more than one attack there was 1 from the United States who had been 8 months on the Isthmus, 1 from the United States who had been 14 months on the Isthmus, 1 from the United States who had been 18 months on the Isthmus, 1 from Jamaica who had been 21 months on the Isthmus, 1 from the United States who had been 2 years on the Isthmus, 1 from the United States who had been 2½ years on the Isthmus, and 1 from France who had been 3 years on the Isthmus. These cases all occurred before July, 1907. With one exception they were all among whites.

The time of habitation on the Isthmus before admission to the hospital with positive symptoms varies. The greater number were admitted after a residence of 3 to 9 months, though a number as early as one month after arrival. Under one month: 2 from the United States, 1 from Grenada, 1 from Dominica, 1 from Jamaica, 1 from Spain, 1 from Colombia, 1 from Trinidad, 1 from Sweden, 1 from Guadeloupe. Total 10. One to two months: 4 from Jamaica, 3 from Guadeloupe, 1 from St. Lucia, 1 from Barbados, 1 from Grenada, 1 from Colombia, 1 from Antigua, 1 from the United States. Total 13. Two to three months: 5 from Barbados, 2 from Guadeloupe, 2 from France, 1 from Montserrat, 1 from Grenada, 1 from Jamaica,

1 from the United States. Total 13. Three to six months: 12 from Barbados, 4 from the United States, 3 from Guadeloupe, 3 from Jamaica, 1 from Antigua, 1 from Venezuela, 1 from Spain, 1 from West Indies, 1 from Fortune Island, 1 from Martinique, 1 from St. Vincent. Total 29. Six to nine months: 8 from Barbados, 5 from the United States, 4 from Jamaica, 2 from Spain, 1 from France, 1 from St. Thomas, 1 from Colombia, 1 from Antigua, 1 from Ireland, 1 from St. Lucia, 1 from Canada. Total 26. Nine to twelve months: 5 from Jamaica, 4 from Barbados, 2 from the United States, 1 from Trinidad, 1 from Cuba, 1 from England, 1 from Martinique. Total 15. One year to eighteen months: 7 from the United States, 2 from France, 2 from Spain, 3 from Barbados, 1 from Greece, 1 from Canada, 1 from Italy, 1 from Venezuela, 1 from Jamaica, 1 from Grenada, 1 from Hayti. Total 21. Eighteenth months to two years: 7 from Jamaica, 5 from the United States, 5 from Barbados, 1 from Antigua, 1 from Colombia, 1 from Guadeloupe. Total 20. Two to three years: 4 from Jamaica, 3 from the United States, 2 from France, 3 from Martinique, 5 from Barbados, 1 from Antigua, 1 from St. Kitts. Total 19. Three to five years: 2 from the United States, 2 from Jamaica, 1 from Mexico. Total 5. Five to ten years: 2 from Colombia, 1 from Martinique, 1 from Jamaica. Total 4. Ten to twenty years: 3 from Jamaica, 2 from Colombia, 1 from France. Total 6. Twenty years and over: 6 from Jamaica, 1 from the United States, 1 from Italy. Total 8. Life: 5 from Panama. Total 5. Unknown: 17. Total 211.

When comparing the mortality and severity of the cases under early and late treatment it can be seen that though many presented or acquired severe complications even when admitted early after the onset, yet a greater number of those admitted late in the course of their attack and necessarily obtaining late treatment developed severe complications and proved fatal.

Ill When Admitted	Number Admitted	Deaths	
1 day	3	0	
2 days	17	0	
3 "	11	2	(1 having parotitis, liver abscess, ulcerated colon, cecostomy).
4 "	19	2	(1 with lobar pneumonia and multiple abscess of liver—1 with malaria tertian).
5 "	18	3	(1 had a cecostomy operation, ulcer of the appendix and peritonitis—1 malarial double tertian.)
6 "	12	2	(2 had ulceration of the colon and appendix).
7 "	17	3	(1 perforation of the sigmoid, peritonitis estivo-autumnal malaria—1 ulceration of the colon and appendix and peritonitis—1 malaria tertian and purulent sinusitis).
8 "	13	9	(1 malaria estivoautumnal—1 abscess of the liver, parotitis, malaria tertian, ulcer of the colon—1 sinusitis—2 ulcers of the colon and appendix—1 syphilis—1 ulceration of the colon, ulceration of the appendix, acute peritonitis, and multiple abscess of liver).
9 "	3	1	
10 "	10	3	(1 perforation and uncinaria—1 abscess of the liver, uncinaria and chronic nephritis).

9 weeks	2	1	
3 months	4	2	(1 liver abscess and ulcer of the appendix).
4 "	1	1	(multiple liver abscess, perforation of the colon and peritonitis).
Unkn'wn	20	3	(1 general peritonitis).

In all 56 deaths, of whom 37 had complications severe enough to cause death by themselves.

Hence among the deaths there were from: Abscess liver, 13; ulcertation colon, 13; peritonitis, 9; ulceration appendix, 8; perforation, 5; sinusitis, 4; cecostomy, 4; parotitis, 2; lobar pneumonia, 1; empyema, 1; abscess of lung, 1; retrocecal abscess, 1; syphilis, 1; chronic nephritis, 1; uncinariasis, 4; uncomplicated, 19.

Complications among those who recovered were: Malarial fever estivoautumnal, 15; malarial fever tertian, 6; uncinariasis, 5; lobar pneumonia, 2; abscess of liver, 1; cecostomy, 1; phlebitis, 1; chronic nephritis, 2; acute nephritis, 3.

Four uncomplicated cases died under the method recommended, with an average period in the hospital of 5½ days, showing the acute condition on admission. Eleven uncomplicated cases died by other methods of treatment, with an average of 22 days in hospital.

Leucocyte counts were not generally made. In cases complicated with liver abscess they were 39,000, 17,200, 15,000, 10,800, 30,000, and 14,800.

The polynuclear count varied from 73 per cent. to 90 per cent.; when complicated with lobar pneumonia 18,800 and 32,000. In two, when ulceration of the colon alone was present 4,800 and 3,200, thus simulating typhoid fever. In other apparently uncomplicated cases which recovered 34,000, 22,000, 21,800, 13,200, 10,600, 9,600, 8,000, 7,600, 7,000, and 5,500 were made.

In regard to the treatment, a variety of methods have been tried in this hospital with varying success. They resolve themselves into oral medications and local treatment in the form of irrigations. Among the former may be mentioned castor oil, magnesium sulphate, opiates, ipecac, and bismuth, with combination particularly of bismuth and opium. Among the latter, quinine irrigations in varying strengths, but usually 1 in 500, thymol irrigations 1 in 2,000 or 3,000, combinations of both, silver nitrate ¼ per cent. boric acid, starch, starch and laudanum, tannic acid, copper sulphate, normal salt, and plain water, warm and cold.

Of all the different methods used, one stands out preeminently, that is, bismuth by the mouth and simple irrigations, either normal saline or plain water per rectum. The method is simple, harmless, and physiological, and as our statistics show, more than justifiable. Of 129 cases treated by this method, there were 24 deaths, or 18 per cent., with an average time in the hospital of 21 days. By the other methods, there were 82 cases, with a mortality of 32, or 39 per cent., and an average time in the hospital of 28 days.

The treatment herein recommended may be termed the rest-supportive treatment. Absolute rest is enjoined, an absolute milk diet, of which there should be an abundance, saline or water irrigations, and bismuth subnitrate in heroic doses. We do not object at the beginning if tenesmus and distress be very severe to an occasional hypodermic of morphine and atropine, but as a routine measure it is not considered good treatment.

If we consider the conditions present in a severe amebic dysentery, we find first a lowered vitality; second, local lesions, confined chiefly to the large bowel and consisting mainly of undermined sloughing ulcers with ragged, more or less necrotic mucous membrane associated with irritating discharge. In the borders of the undermined ulcers encroaching on sound tissue and thoroughly protected from in-

testinal contents are the amebæ exercising their cytolytic action on healthy cells. From these ulcers numerous amebæ are thrown off in the discharges and these alone can we hope to destroy by any amebicidal agent.

With these pathological conditions present how can we best attempt to relieve the patient? In some respects amebic dysentery acts like malaria. An individual may have latent malaria for months and years and enjoy perfect health because of the natural resistance and immunity established, but granted an operation, shock, overexertion, fatigue, an anesthetic, or anything to happen by which his resistance is temporarily lowered, immediately the malarial organisms reassert themselves. As we often see here, it is almost impossible to cure a malaria during a typhoid fever attack until the convalescence from the latter is established and his resistance reaches a point to be able to cope with it.

The modern methods of dealing with tuberculosis are not by endeavoring to destroy the tubercle in the tissues, but are directed altogether to increase the patient's natural resistance, and amebic dysentery should be treated in the same way.

How can we hope to recover the natural resistance of the body and overcome the pathological amebic process? It is evident from the pathological character of the lesions and also the situation whence the amebæ extend their destructive processes that local amebicidal irrigations are futile, except in so far as they may destroy those amebæ that are liberated and are free in the lumen of the bowel. It is impossible to reach the living, active, deep-seated ones that are invading sound tissue in the walls of undermining ulcers. These ulcers have comparatively small openings in the early stages, so small that solutions could not gain access. Moreover, solutions which irritate the bowel only favor the invasion of fresh areas. For these reasons we prefer normal saline solutions or plain water because it lavages the mucous membrane of the bowel, removing the irritation and toxic discharges. From two to four times daily this is recommended.

The next point for consideration is the diet. An absolute milk diet is recommended because (a) it is a perfect food; (b), because intestinal putrefaction is less marked in this than any other diet. In order to appreciate this latter point certain physiological points on digestion are of prime consideration when taken in conjunction with the observations of Musgrave, Clegg, and others, that amebæ only flourish when associated with microorganisms.

Changes in food stuffs after entering the alimentary canal are subjected to two main classes of fermentation, the unorganized or enzyme ferments and the organized ferments, or that due to fermentative or putrefactive bacteria. In the first group we have ptyalin, pepsin, rennin, trypsin, amylopsin, steapsin, and invertin. In the latter group a great number of microorganisms which have a physiological importance in converting excess of food stuffs into products which can be assimilated or elminated, as gases, complex organic compounds, or insoluble excreta. In the stomach and small intestine the organized ferments act chiefly on the carbohydrates, but in the cecum and large intestine the putrefactive bacteria play their great rôle on the proteins and their partially converted products. The large intestine has three chief functions: (1) that of being the chief receptacle where putrefactive and fermentative bacteria exercise their functions; (2) an organ of absorption where the liquid products of digestion are finally absorbed, and (3) where the non-assimilable products along with mucoid secretions are formed into feces.

In amebic dysentery with its ulcerative bowel lesions in the large intestine it is therefore necessary to limit bacterial action as much as possible as it favors the development of the amebic processes.

It is because milk is the least prone to this fermentation and that it is practically all absorbed before it reaches the large intestine that it is the ideal diet in amebic dysentery. Eggs for these reasons are contraindicated.

The digestive processes in amebic dysentery are interfered with as they are in typhoid or any febrile process. The gastric, intestinal, and visceral secretions are lessened or absent, so that enzyme digestion is much enfeebled and bacterial fermentation is accelerated. An excess of protein is always taken care of in the large bowel by the putrefactive bacteria. When, as in amebic dysentery, the enzyme digestion is largely in abeyance any increase of the protein over a physiological diet merely furnishes so much more pabulum for the bacteria in the large intestine which in turn favor the growth of amebæ. For these reasons during convalescence when a pure milk diet can be departed from, the carbohydrates and hydrocarbons are added to the dietary before the protein.

We now come to a consideration of the oral medication. A preliminary dose of castor oil is given to free the bowel of all products of fermentation. It is more thorough and less irritating than magnesium sulphate. In doubtful cases the administration of a dose of the latter is good because it favors the appearance of amebæ in the stools. If the ulceration be far down in the rectum, producing a great deal of tenesmus and distress, an occasional hypodermic of morphine and atropine is administered. We do not favor the routine administration of opium for two reasons: (a) because it interferes with production of enzymes and enzyme digestion, and (b) because it lessens the peristaltic action of the bowel, thus favoring the retention of toxic products which are harmful in sound mucous membrane and whose elimination is indicated.

The only other medication used here is the subnitrate of bismuth in heroic doses. We give a drachm or a drachm and a half by measurement (three drachms by weight), stirred in a glass of water every three hours till there is a general improvement, which is from three to ten or at most fifteen days.

How does bismuth act? (1) As it is largely insoluble it passes through the bowel coating over the mucous membrane as acting as a mechanical sedative and astringent. (2) Theodore Kocher, in 1883, demonstrated that insoluble preparations of bismuth were actively antiseptic. To this feature I attach the great value of the subnitrate salt in the treatment of amebic dysentery. It thus destroys or inhibits bacterial fermentative and putrefactive processes which favor the growth of amebæ while not interfering with enzyme digestion throughout the alimentary tract. We have never seen here the toxic effects ascribed to bismuth subnitrate when administered in large doses.

The course of the disease under the above-mentioned methods of treatment varies with the severity and chronicity. In the milder cases convalescence begins on the third or fourth day, but usually toward the end of the first week. In the severer cases ten days or a fortnight may pass before the stools

begin to lessen, and the tongue clean. The patients must be carefully watched and if the well-known symptoms suggesting toxicity arise as manifested in the pulse, tongue, and general condition, surgical interference must immediately be sought and a wide-open cecostomy be performed after the method pursued here by Dr. Herrick. When convalescence is established the main point then is to adopt every measure to increase the natural resistance of the patient. The more this is attained the less prone are we to relapses.

One chronic case that had contracted the disease in October, 1897, and had consulted with a great many physicians in different cities in the United States, and was advised as many different methods of medication, and with one of whom he spent a year taking special treatments of irrigations and internal medication without benefit, reported here for treatment on June 16 of last year. He informed me that during this period of almost eleven years he had formed movements during a period of 6 days only and was a constant sufferer from weakness, pain in the legs, and tenesmus. He averaged about eight movements a day and generally with blood and mucus. On his admission the stools were characteristic and contained many large active amebæ. He was put on the treatment above recommended, viz., rest in bed, a milk diet, bismuth subnitrate, a teaspoonful every three hours, and saline irrigations. Before he left the hospital his stools were formed. At his own request he was discharged on June 28, twelve days after admission, feeling very much stronger and practically well. He continued to take bismuth, however, off and on for two months and adhered to a diet largely free from protein. During this time he remained actively at work. I saw him professionally about a month ago with an attack of malaria, when he informed me that he had been perfectly well of his dysentery since August one year ago. I might mention a number of other cases with similar happy results, two of which contracted their trouble in the Philippines and one in Brazil. They were very chronic cases.

On looking carefully over our charts we find not a single case of relapse since this method of treatment has been adopted. On the other hand, in 1905, 1906, and the early part of 1907, recurrences took place when the quinine thymol irrigations and other methods were in vogue and opiates were freely administered.

Of the complications mentioned above, one stands out preeminently, viz., abscess of the liver. It may develop without dysenteric symptoms and even when they have been in abeyance for years. On the other hand, it frequently occurs when the dysenteric process is acute, obscuring the symptoms, and causing a rapid fatal termination. It has been frequently overlooked here because of the preeminence of the dysenteric affection. It is in these conditions of acute dysentery that the multiple abscesses occur. Resistance is at a low ebb and a perfect shower of amebæ enter the portal circulation forming miliary necroses and subsequent abscesses. We hope later on to discuss the symptomatology of liver abscess more in detail.

Of the other complications mentioned above, little need be said. As one can readily see, they occur more frequently and are more fatal the longer active treatment is delayed. The sooner the dysenteric symptoms are recognized the greater hope we have of a favorable issue and a perfect cure.

We think that the statistics above shown are ample justification of the method here pursued, particularly when we consider that of the 31 cases treated this year the mortality is but 6.5 per cent., and it is only during this period that the method has been rigidly adhered to and the heroic doses of bismuth subnitrate administered. The treatment is merely a plea to aid nature to reassert itself by physiological means, by rest, nutritive support, and the simple harmless medicaments above mentioned.

Summary: (a) No race or nationality is immune to the disease. (b) There is no endemic local center. (c) The frequency of cases usually run in successive months, but not at the same periods of the year, and the number varies greatly in successive years. (d) Complications are numerous, but the most common is abscess of the liver. (e) The longer treatment is delayed the more grave is the prognosis. (f) The rest-supportive treatment, consisting of rest in bed, a milk diet, the use of mild irrigations, and bismuth subnitrate in heroic doses, has given here by far the most satisfactory results. (g) Surgical interference is indicated if improvement does not rapidly follow the above-mentioned method.

THE SURGICAL TREATMENT OF VERY SEVERE AND LATE CASES OF AMEBIC DYSENTERY.*

By A. B. HERRICK, M.D.,

CHIEF OF SURGICAL CLINIC, ANCON HOSPITAL.

The surgical treatment of dysentery was first suggested by Hale White in 1895, who recommended an artificial anus on the right side to give the colon rest and afford an opportunity for local treatment in cases of intractable ulcerative colitis. This operation was never greatly used on account of the disagreeableness of the artificial anus to the patient and the uncertainty of the ultimate closure, as well as the dangers attending the operation itself.

Accordingly it was modified by Gibson, who adopted the Kader method of valve formation, thus producing a valvular cecostomy through which local treatment could be given. In 1902 another operation was advised by Weir of New York, by utilizing the appendix in the treatment of this condition. This operation—known as appendicostomy—is now generally accepted in the literature to be the best surgical treatment of intractable dysentery.

Thus we see that the tendency of the past has been to go from cecostomy to appendicostomy, though it must be remembered that the cecostomy operation advocated by the earlier writers was, as a rule, for the purposes of irrigation only, and that the cecostomy as usually performed, accomplished only the same result that was obtained by the operation of appendicostomy.

Cases of dysentery as turned over to the surgeon by the clinicians come under the following classifications:

First: Those that have become chronic and remain in this condition under the best medical treatment. The great majority of the cases in the literature come in this class and most excellent results have been obtained by means of appendicostomy with the subsequent treatment attained by its aid. In this hospital I have had practically no cases in this class, as they have reacted so favorably to the medical treatment employed that surgical intervention was unnecessary.

*Read before the Canal Zone Medical Association, August, 1909.

Second: The second class comprises those cases of acute, fulminating type, which represent a severe form of the disease, and in which from the very onset the extreme toxicity of the process is so marked that in the near future the clinician will advise combined surgical and medical treatment from the start. This is a class of cases whose members will increase with the acumen of the clinician in his diagnosis and prognosis of the individual cases.

Third: The third class includes those of a severe, acute type which are resistant to medical treatment, and at the end of one or two weeks no improvement is found, or the patient is failing—and in this class would fall practically all the cases which have been turned over to the surgical side in this hospital.

In the treatment of these severe forms of dysentery, I believe that three things are necessary: (1) Supportive treatment of the patient which would include the various hygienic and medical measures usually employed; (2) local treatment of the large bowel, which is partially obtained by rectal irrigation through the appendix or valvular cecostomy according to the Kader method, and (3) a complete rest of the large bowel from all irritation of food particles or decomposition products thereof passing over its surface. The significance of this third point can be readily understood if we consider the value of an artificial anus in cases of ulcerative proctitis or cancer of rectum and the marked improvement in these cases after the irritation of the bowel contents is removed.

This raises a question as to the way in which the dysenteric toxin is elaborated and absorbed into the system. Is it a process which takes place in the wall of the bowel only, or does it occur on the surface of the bowel also, or, still further, is there an elaboration in the bowel cavity with an interrelation with the various bacteria acting on the food products, thereby producing unusual ptomains and decomposition products which might play a roll in the clinical manifestations of dysentery? That these different elements enter into the diseased process will be proved, I believe, by a study of a large series of cases treated by surgical methods. For in cases of dysentery treated early by irrigation through an appendicostomy or cecostomy at a stage when the diseased process is still mainly on the surface layers of the bowel, it will be found that there is a marked amelioration in all the symptoms and toxicity of the disease, but in cases delayed until the process has reached the deeper layers of the bowel, there will be much less improvement and far more reliance will have to be placed upon supportive measures.

Accordingly in the severe forms of dysentery, the rôle that these three methods of treatment play should be carefully borne in mind, because only by a proper adjusting of all three can we do the utmost for the patient. The first two of these is readily accomplished by the operation of appendicostomy and is well shown by Curl's report from Colon Hospital of eleven cases of severe dysentery in which he performed this operation, upon admission of patients to hospital, or shortly afterward, with only three deaths. To obtain the third requisite, that is, the complete rest of the large bowel, necessary in the most severe forms of dysentery, a larger opening is required and one sufficient to allow the contents of the cecum to be evacuated at that point.

The operation of cecostomy as performed here is very simple, consumes very little if any more time, and often can be done quicker, than the corresponding operation of appendicostomy. An incision three inches long is made directly into the abdominal cavity over the region of the cecum. The cecum is grasped and drawn into the wound and two of its longitudinal bands are attached to the parietal peritoneum, one on either side of the incision by a running catgut suture, thus shutting off the general peritoneal cavity and leaving a large pouch of the cecum protruding through the wound. A few interrupted catgut sutures anchor this pouch to the skin, iodoform packing being introduced between for the sake of drainage and to shut off contamination of the muscle layers. The cecal pouch is opened at once, the contents sponged out, and irrigations can be started immediately. In my earlier operations I fastened a large tube in the ileum, but I found later that the cecum with its mucous membrane would evert itself, thus allowing the ileum to discharge its contents practically outside the wound. I always open the cecal pouch at the time of the original operation, and, although this is considered a hazardous proceeding, I have had no bad results arise therefrom in my series of cases. The operation can be performed either under local or general anesthesia. Both methods have been used here, but in these very severe cases my preference is for a local anesthetic.

With the exception of one of the earlier cases, all of this series were transferred to the surgical side as being in a most critical condition, and some of them practically moribund. In four of the cases the operation was practically bloodless, the patient's vitality being so low that the operation could have been performed with a knife, scissors, and thread. The series comprises eleven cases, four of whom recovered. In four of the cases there were liver abscesses in the multiple form, mainly of the small terminal variety, which of course would be hopeless under any form of treatment. Another case was complicated with pulmonary tuberculosis and died one month after the operation with marked tuberculous lesions of the lung, a dysenteric process still persisting in the bowel. Two other cases resulted fatally, one operated on the twenty-first day died six days later; the other operated on the twenty-ninth day died three days later; each of these complicated by a bronchopneumonia. In these two cases, the operation was performed under cocaine anesthesia.

In the four cases that recovered, three of them represent a very severe type of the disease, and the charts show the marked amelioration beginning immediately after the operation. The fourth case is one who had chronic dysentery for five months, then developed an acute exacerbation and was operated on ten days later, and in this case it was four months before the cecostomy was closed. He was seen again seven months later and there was no return of the process.

The objections that have been hitherto raised to this operation are: (1) The difficulty of performance; (2) the disagreeableness to the patient of the artificial anus; (3) the starvation of the patient on account of insufficient nourishment due to the absorbing surface of the large bowel cut off; (4) the difficulty of closure.

As to the difficulty of performance, I believe there is very little difference between this method of cecostomy and appendicostomy. As to the disagreeableness to the patient of the artificial anus, I do not think that should be considered, for these cases were practically moribund. As to the starvation of the patient, we know that there is a marked

diminution in the nutritive absorbing powers of the colon when a large part of its surface is diseased: also, with an artificial anus we do not have to exercise the same care in dieting of our patients and can give them a far more liberal diet, only taking care that the food is easily digested and absorbed. These patients all became well and strong even with the large bowel sidetracked by means of the cecostomy.

The closure of the cecostomy, when performed by the method above described, is very simple. The mucous membrane of the incision is united and this turned in by an interrupted suture approximating the serosa. The wound is then closed, layer by layer. In spite of the large opening the abdomen was strong in these four cases at the time of discharge, and two of them have been examined since, after being at hard work, and the closure found perfectly strong.

These cases are too few to draw any conclusions from, but they serve to show that many of the acute and rapidly fatal cases of dysentery could be saved by early surgical intervention. From a study of these cases, I believe that a case of severe fulminating or acute, intractable, ulcerative colitis should be given the additional chance afforded by the sidetracking of the large bowel even though he has hippocratic facies and is in a moribund condition, although, of course, better results could be obtained if this operation was performed earlier. This operation, however, will be of no service in cases where other complications have set in, such as the terminal multiple abscesses of the liver.

PATHOGENESIS OF TABETIC ARTHROPATHIES BASED UPON AN ANATOMO-CLINICAL STUDY OF TWO CASES.*

By ALFRED GORDON, M.D.,

PHILADELPHIA, PA.

NEUROLOGIST TO MOUNT SINAI, DOUGLAS MEMORIAL AND NORTHWESTERN GENERAL HOSPITALS.

Diseases of joints in the skeleton occurring in the course of tabes and due partly or totally to the after-effects of the tabetic process are well known. Since Charcot's first clinical and anatomatical description of the condition in 1868, a number of observations followed and arthropathies have been observed not only in the large joints of the lower extremities, but also in those of the upper extremities and their small joints (carpal, metacarpal, tarsal, metatarsal, phalangeal), finally in the joints of the skeleton of the face. In 1884 G. Kroenig (*Zeitschrift für klin. Medicin*, 1884) also called attention to arthropathies of the vertebræ in tabes. J. Abadie, in 1900 (Nouvelle Iconographie de la Salpêtrière) described a large number of cases of the latter condition. Almost every articulation of the skeleton therefore may become involved in tabes. Of course, some joints are more frequently involved than others. The knee and ankle present the largest number of cases. The tarsus is next in frequency. The hip is oftener affected than the shoulder. The small joints of the limbs and the vertebræ are rarely involved.

The anatomical condition of such joints has been well studied by various writers and among recent descriptions that of Idelsohn's may be particularly mentioned, as it gives a detailed and minute account of the joint itself, also of the surrounding tissues. In spite of this large accumulated material the cause and the exact pathogenesis of the morbid process remained unknown.

Attempts have been made from time to time by very competent observers to find a causal relation between the diseases of the joints and various histological elements affected by the tabetic degenerative process. Charcot and his followers incriminated the cells of the anterior cornua in the spinal cord. They thought that these cells contain neurotrophic centers for bones and articulations. They reported some cases in which the gray matter of the anterior cornua was found deformed, atrophied, diseased, but at the same time they wisely cautioned against the final acceptance of this view before a sufficiently large number of cases has accumulated showing the constancy of such findings. After the publication of four positive cases by Charcot, Pierret, Lionville, Joffroy and Condoléon, soon seventeen cases appeared in the literature with diametrically opposite findings. They are those of Bourceret and Coyne (1 case), Raymond (2), Pitres and Vaillard (6), Oppenheim and Siemerling (3), Paulidis (1), Marinesco (1), Bouglé (2), Pitres and Carrière (1 case) (see collection of Pitres and Carrière, Archives Cliniques de Bordeaux, 1896). The records of subsequent writers also show a great diversity of findings, some directly opposite to others. Besides, in some of the cases in which atrophy of cells in the anterior cornua was found, the segment of the cord involved did not correspond to the joint affected.

The theory of a center for nutrition of bones or joints is certainly an attractive one and one is apt *a priori* to ascribe the lesion to a trophic center in the cord, but direct evidences for its existence have never been brought forward. All these reasons, I believe, amply justify a complete abandonment of the spinal theory of the arthropathies. For the same reason Buzzard's theory as to the existence of an articulation-center in the medulla cannot hold ground.

The next question in the history of joint-lesions of tabes was the state of the nerve trunks which supply the articulation with nerve fibers. Much attention has been given this subject. It is a well-known fact that the peripheral nerves are frequently affected in tabes. In view of this frequency a suggestion was made that there are trophic fibers in peripheral nerves and that the diseases of the joints are due to the degenerative state of those trophic nerves. A careful search in the literature fails to reveal any histological of physiological evidence as to the existence of such nerves for bones and joints. Sherrington distinctly says that there is no proof of nerves with a specific trophic influence and that every nerve center that can influence the proper and specific activity of a tissue possesses in so far a trophic influence on that tissue (Schäffer's Physiology). It is not at all necessary to appeal to imaginary trophic fibers. The mere existence of a degenerative state of peripheral nerves the majority of which is composed of motor and sensory fibers is sufficient to explain the dystrophy of the joints. That the sensory nerves are affected, is evident from the defective perception of pain in the skin and in the affected joints. A Charcot joint can be moved in various directions without provoking much pain or any pain at all. It is evident that the deep sensory fibers are involved. There are a great many observations on record in which the nerves entering the affected joints were found diseased.

On the basis of the "sensory nerve theory" Mari-

*Read before the American Neurological Association, May, 1909.

nesco (*Revue Neurologique*, 1894) advanced the following proposition. The normal nutrition of tissue provokes in the sensory terminations excitations which are transmitted to the vasomotor centers of the cord. The latter in their turn provoke a reflex influence at the periphery and thus maintains a normal tonus necessary for the nutrition. If for any reason the sensory nerves of the joints are altered, an insufficiency of vasomotor reactions is created and trophic disturbances follow. Mouchat and Coronat also admit that when an insufficiency of sensory stimulation exists, the arthropathy is of a trophic type; the hypertrophic type is the result of the compensatory process of those sensory fibers which remained intact and consequently they over stimulate the vasomotor centers of the cord. Tabetic arthropathy consequently is readily explained by the diseased state of the sensory nerves which are so frequently found to be degenerated in tabes. This view is simply based on the common observation, viz., that the nutrition of a tissue depends on the vital state of a nerve distributed in that tissue.

So simple and clear as it may appear, the neuritic pathogenesis of the tabetic arthropathies cannot be accepted as the sole factor. There are on record cases in which the most thorough examination failed to find any track of degeneration in the peripheral nerves. Such are the cases of Chipault, Damaschino, Bellangé and more recently of Henderson (*Journal of Pathology and Bacteriology*, 1905). It is true that in the largest majority of tabetic cases the peripheral nerves are involved, but the fact that in some cases, even if they are very few, no lesion was found, weakens somewhat the exclusive incrimination of the peripheral and articular nerves in causation of joint lesions. Moreover, what is well established, is the fact that the terminal nerves are equally affected in tabes on the side of the arthropathy as well as on the side without a joint lesion. Besides, the number of cases with arthropathies in tabes is comparatively very small, and according to Gowers only 10 per cent. The latter fact militates strongly against the neuritic theory, as it is surprising that in view of the great frequency of nerve changes in tabes the number of arthropathies are not equally frequent.

En résumé we can say that in spite of the simplicity of the view that the peripheral nerves are the direct cause of tabetic arthropathies this view cannot be accepted in its entirety because of (1) absence of nerve lesions in some cases, (2) presence of nerve lesions in the affected and non-affected joints, (3) the very small percentage of arthropathies in tabes. Should then the influence of diseased nerves be abandoned in considering the pathogenesis of arthropathies?

When a tissue or an organ is found in a pathological state and the nerves distributed in it are found diseased, the rôle the latter played in the causation of the former cannot and should not be ignored. As in the tabetic arthropathies the influence of the nerves alone cannot be admitted, an additional element must be sought for.

Volkmann advanced a view that trauma is the direct cause of the condition. Indeed if we consider the marked deficiency in the general sensibility, the diminished sense of pain in the skin and in the joints, the loss of reflexes, the hypotonia of muscles and ligaments leading to their abnormal display, the enormous strain of the limbs, joints and ligaments during and because of the ataxia, for all these reasons we must admit that trauma of a joint is an easy occurrence in tabes. Regnard, according to Henderson, reports a case in which tossing in bed and a brusque incoordinate movement of a limb while in bed ended in an arthropathy. Consequently without an apparently direct and gross injury, a joint may undergo an undue stretching, twisting or a slight unobservable trauma and commence a pathological process which rapidly or slowly will lead to a typical tabetic arthropathy. These traumata may occur not only in the ataxic period and because of the incoordination, but also in the preataxic stage. In the latter case the loss of pain-sense and of reflexes are sufficient causes for traumata. The latter may for the same reason pass unnoticed. A trauma consequently is an important factor in the etiology of tabetic arthropathies. When a trauma occurs in a joint, the nerve supply of which is undergoing degeneration, the pathological condition of the former is easily conceivable.

Not only recent but also old traumata may become the point of departure for tabetic arthropathies. H. Claude reports such a case in the *Revue Neurologique*, 1907. A mason, 38 years of age, dislocated his hip at 14; had a contusion of the right foot at 18 and a sprain of the left knee at 30. He contracted syphilis at 28. At the age of 34 the first symptoms of tabes made their appearance. Since then the disease progressed and at 38 he presented a complete picture of the most typical form of tabes. He presented also arthropathies of the hypertrophic form in the right hip, left knee and right foot. They were confined precisely to the parts which were the seats of the old traumatic distrubances which had occurred 24, 20 and 4 years prior to the onset of tabes. That the traumata of old date contributed here to the ultimate development of the arthropathies cannot be denied.

The following two cases which I am about to report are exceedingly important, I believe, from the standpoint of a traumatic origin of arthropathies in two tabetics, whose peripheral and articular nerves have been in a state of degeneration. A most careful anatomical and histological study has been made. The most minute nerve branches around and in the articulation have been dissected with the utmost care. The corresponding blood-vessels, large and small, were equally removed and prepared for examination. For the purpose of control an identical number of nerves and blood-vessels were dissected, removed, and examined on the unaffected sides. Two knees with large portions of the constituting bones, also two feet with their ankle-joints were totally removed and carefully dissected and anatomically examined. The spinal cords and medullas were very carefully examined as to the tabetic tracts also for cells in the cornua and the anterior and posterior roots. No nervous element has therefore been neglected. A very large number of specimens has been prepared and repeatedly examined.

Case I.—Frederick S., tailor, 39 years of age, contracted syphilis at the age of 20. Seven years later began to suffer from vague pains in the lower extremities which he attributed to rheumatism. A year later he noticed that occasionally he would see double. The former vague pains became more definite: they became lancinating and very sharp. Two years later ataxia appeared in the lower limbs. The condition gradually grew worse until three years ago when he first came under my observation. He then presented the following picture: marked ataxia of the legs, loss of patellar and

Achilles' tendon reflexes, Romberg's sign, Argyll-Robertson pupils, optic atrophy, palsy of the left internal rectus, difficulty of micturition, sexual impotence, hypesthesia to touch and pain in the four extremities, and marked hypotonia of the lower limbs.

Apart from the usual hygienic, dietetic, and iodide treatment, the patient was advised to take up a course of systematic exercises. During four months the latter was kept up and the improvement of the ataxia was remarkable. He was able to walk without assistance. One afternoon while exercising in his room for turning around with closed eyes, his right knee received a sudden twist. He immediately felt pain. At the end of ten days the latter has considerably subsided, but he was no more able to use his right leg as previously. A slight swelling was soon noticeable on the inner side of the knee which kept on increasing. While some pain persisted, passive manipulations were not only possible but even caused very little discomfort. Soon a decided enlargement of the entire knee began to be visible. No external applications or rest could arrest the progressive increase in size. At the end of eighteen months the joint was very large. The bony structures surrounding the joint were much enlarged; there was some effusion in the joint. The skin around it was thick and presented a peculiar firm edema. The patient contracted pneumonia five months later and died.

At autopsy the affected joint presented stretched ligaments and capsule, thickened synovial, a moderate amount of fluid, considerable enlargement of both condyles and head of the tibia, a velvety appearance of the cartilage which in a few places was absent and the bone was then exposed. The following parts were removed for a microscopical examination: the cord with portions of its roots, the medulla, some peripheral nerves and blood-vessels (see later). The medulla was found normal. A cervical, thoracic and lumbar segment of the cord were examined very carefully. The cells of the cornua were stained with thionin and ammonia-carmin. Repeated examinations of a large number of sections revealed nothing abnormal in the cells; the latter were normal in their aspect, dimensions and form. Slight alterations were found in the posterior cornua; some cells were missing. The posterior columns showed the usual degeneration and sclerosis characteristic of tabes. The posterior roots also presented distinct degenerated areas although the destruction was not complete.

Great care and considerable time were spent on dissection of portions of the following nerves which were subsequently examined with the methods of both Marchi and Weigert: (1) In the popliteal space the tibial nerve (internal popliteal), the superior and inferior internal articular and the azygos articular, a branch that is given off from the nerve to the popliteus muscle, and which goes to the knee and the superior tibiofibular joint; (2) below the popliteal space a branch that arises from the tibial to pass into the joint through the internal lateral ligament; (3) from the external popliteal n. two articular branches, upper and lower, also a recurrent articular nerve which goes around the neck of the fibula to the knee-joint and tibiofibular joint; (4) a portion of the external popliteal at the apex of the popliteal space, also of the same nerve before it breaks up into its three terminal branches (recurrent articular, musculocutaneous, and anterior tibial).

All the articular branches were cut off with portions of the nerves from which they arise. For the purpose of control the knee-joint of the unaffected side was also removed, equally careful dissection was made for the above enumerated nerves and stained with both methods.

The microscope revealed alongside of normal fibers also degenerated areas in all the large and small nerves of both joints with this exception, however, that there were more normal fibers in the internal popliteal nerve (in the popliteal space) on the normal side than on the affected. This quantative difference is negligible, as all other nerves were equally affected on both sides. The difference could be discerned only with the Marchi method, but not with the Weigert.

The following blood-vessels have been dissected and examined microscopically. A portion of the popliteal artery, superior internal articular arteries, azygos articular, inferior external and internal articular arteries; an upper portion of anterior tibial artery, the recurrent tibial posterior, a branch to the superior tibiofibular joint. Similarly to the nerves they were also removed from both knees. The stain employed was ammonium-carmin or hemalum.

A large number of specimens was examined and with very few exceptions they were found normal. Some thickening of the intima and narrowing of the lumen was found in the anterior tibial and popliteal arteries, but no changes in any of the articular branches. The condition was identical in the normal and in the affected knee.

Case II.—John C., coachman, aged 44, contracted syphilis at 29. Twelve years later a tingling sensation made its appearance in the soles of his feet; he then began to complain also of a numbness in his feet and of a sense of softness on the hard ground. Soon sharp pain developed in the legs. This was followed by double vision, difficulty of micturition complicated by imperative micturition, ataxia in the lower limbs. At the end of six months a complete picture of tabes was present. At the time of my examination in addition to the above symptoms there were also loss of patellar and Achilles' tendon reflexes, double optic atrophy, objective sensory disturbances in the lower extremities (hypesthesia to touch, pain and temperature), hypotonia, and some ataxia in the upper extremities. He also presented gastric crises of an unusual severity which could be controlled only by opiates. The usual medicinal treatment was instituted, also systematic exercises for his limbs were kept up for several months with a great degree of success.

About twenty months ago, while walking on an icy pavement without support, he slipped and fell. The left foot turned under him. He managed to get up without assistance and walked a distance of five blocks. There was a slight pain in the ankle, but the discomfort in raising or extending the foot was greater. Since that time he found himself unable to walk without a crutch. He soon noticed a swelling and thickness of the ankle. Passive manipulations of the joint were possible and caused very little pain. The joint kept on growing in size, the bones surrounding it began to get enlarged so that at the end of a year he presented a typical arthropathic ankle, as described originally by Charcot. The general condition of the patient grew progressively worse. He soon developed gastrointestinal trouble with profuse diarrhœa. Hemorrhoids, from which the patient has been a sufferer for years, bled profusely. The patient died in the midst of uncontrollable diarrhea, gastric crises, sleepless

nights and incontinence of urine. The medulla, spinal cord with its anterior and posterior roots, a number of peripheral nerves and blood-vessels (see below), also both feet with their ankle-joints were removed for an anatomical study.

The diseased articulation was globular, and distended; it contained a certain amount of fluid. The skin over it was thickened. The lower end of the tibia and the internal malleolus were markedly enlarged. Similar thickening and enlargement was also noticeable in the astragalus and to a lesser extent in the scaphoid and cuboid bones and in the external malleolus. The ligaments connecting the astragalus with the internal and external malleoli, also with the calcaneum and the cuboid and scaphoid bones of the tarsus were much stretched. The cartilages were destroyed in some areas and exposed the bony tissue. The ankle-joint of the opposite lower extremity was absolutely normal. The spinal cord on microscopical examination presented the usual degeneration of the posterior columns through the entire cord extending into the medulla. The posterior roots were equally involved, although it contained some healthy fibers. The anterior roots were normal.

Special care was taken in staining the cells of the cornua of the cord. This was done with thionin. A very large number of sections were examined and the cells were found totally normal in the anterior cornua as to their size and form. In the posterior cornua some of the cells presented a state of chromatolysis, the majority, however, were found to be intact.

The following peripheral nerves were carefully dissected and removed for a microscopical study: A portion of the tibial n. immediately before it divides at the level of the inner tubercle of os calcis into two terminal branches; the part of the sural nerve (cutaneous branch of the internal popliteal n.) that goes to the outer side of the foot; a part of the interosseous crural nerve (muscular branch of the internal popliteus) that goes to the inferior tibiofibular joint; the medial calcaneal (branch of the lower part of the internal popliteal nerve) which pierces the internal lateral ligament and is distributed to the integument of the inner side and under surface of the heel; the articular branches coming from the medial plantar nerve and distributed to the astragaloscaphoid and scaphoidocuneiform joints; the articular branches coming from the lateral plantar nerve and supplying the calcaneocuboid, the intertarsal and tarsometatarsal joints; a portion of the anterior tibial immediately before its division at the level of the ankle into its terminal branches; the lateral calcaneal branches (cutaneous branch of the common peroneal nerve) which are distributed to the integument of the outer side of the heel. All these nerves were removed from both ankle-joints and were examined with great thoroughness, a very large number of specimens being used.

The stains used were those of Marchi and of Weigert. The microscope showed considerable degeneration in all those nerves mentioned and almost equally on both sides, viz., in the affected and non-affected joints. What is most remarkable is the fact that the articular branches of the astragaloscaphoid and scaphoidocuneiform joints were more involved on the normal side than they were on the diseased side.

As in the first case, I also examined the blood vessels of both ankle-joints. The following arteries were carefully dissected and removed. The malleolar arteries (internal and external), which supply the ankle-joint; the tarsal artery, branch of dorsalis pedis, which supplies the articulations of the tarsus. The stains used were ammonium-carmin and hemalum. The arteries were found normal in a very large number of specimens.

The two cases just described are very conclusive as to the direct influence of trauma upon the development of arthropathies. But a question arises: Would the disease of the joints have developed had the nerves and the blood-vessels distributed in those joints been normal?

It was important, therefore, to find out if there are cases on record of tabes without degenerative changes in the nerves and blood-vessels, but in which a trauma was followed by progressive arthropathies. A careful search in the literature at my disposal failed to reveal such observations. On the other hand cases of trauma reported have all presented changes in the nerves of the joint. It seems, therefore, that degeneration of the peripheral nerves is a sine quo non in the genesis of tabetic arthropathies, but at the same time trauma is also an indispensable element. We have seen above the strong objections in accepting the neuritis as the only cause of the condition. The histological state of the peripheral nervous system and the gross trauma in my two cases are the best illustration of this contention. My two patients presented sensory disturbances and hypotonia long before the traumata occurred. Their peripheral nerves have undoubtedly been diseased long before the trauma. Moreover, their nerves were found altered on the affected as well as on the unaffected side and until the trauma occurred no evident changes were present in the joint.

Objections may be raised in considering trauma as an important cause of arthropathies in view of the fact that in a number of observations reported trauma has not been mentioned. The latter, in my judgment, does not militate against the above view. The absence of gross and evident traumata does not exclude the possibility of slight or very insignificant injuries to joints which may occur in the course of tabes by virtue of the loss of reflexes, of the hypotonia and of marked diminution of the pain-sense. Claude's case (*loc. cit.*) shows also that old and apparently healed up injuries are apt to become the point of departure for a new morbid process which finds there its locus minoris resistentiæ and therefore attacks it.

The blood-vessels probably also play a certain rôle in the state of nutrition of tissues composing the articulation. Arteriosclerosis is a frequent cause of diseases of joints in general. Not infrequently involvement of blood-vessels, thickening of their walls and narrowness of their lumen have been found in tabetic joints. In the first of my two cases some alteration of the blood-vessels was noticed, but in the second case no changes were found. It is, therefore, evident that while the state of the blood-vessels may contribute to or hasten the pathological process, changes of the latter are not absolutely essential in the causation of tabetic arthropathies. The conclusion to which my two anatomical cases lead, is that the origin of joint lesion in tabes lies mainly in the state of the peripheral nerves, but a provoking cause such as trauma (in its broadest sense) is essential. The blood-vessels play a certain contributory part in its causation, but their changes are not indispensable in the etiology of tabetic arthropathies.

A CLINICAL STUDY OF SIX HUNDRED CASES OF HEART DISEASE.*

By J. N. HALL, M.D.,

DENVER, COLORADO.

PROFESSOR OF MEDICINE IN THE DENVER AND GROSS COLLEGE OF MEDICINE.

I OFFER you to-night a clinical study of 600 cases of heart disease which I have seen in the past seven years, the data all coming from my private records. For the collection and analysis of the records I am indebted to my assistant, Dr. T. R. Love. Every case history and every examination was my own personal work. The errors as to exact diagnosis are doubtless considerable in such a series. In order to minimize them and to allow each reader to form a just estimate as to the probable correctness or otherwise of the diagnoses, I give below a synopsis of what I believe to be requisite for a diagnosis of each of the valvular diseases.

The 600 cases came to me chiefly from the State of Colorado, but a considerable number from Wyoming, Kansas, Nebraska, and other nearby States.

Of the whole number 293 were males, 307 females—a surprisingly even distribution between the sexes. In the first decade there were 16 males and 29 females, in the second 36 males and 52 females, and in the third 52 males and 59 females, in the fourth 56 males and 59 females, in the fifth 44 males and 40 females, in the sixth 47 males and 36 females, in the seventh 31 males and 28 females, in the eighth and ninth 11 males and 4 females. The females preponderated in every decade up to the end of the fourth, and the males thereafter.

It must be noted that, as in many cases there was more than one lesion, our totals overlap in many directions. There were 18 cases of aortic aneurysm; pericarditis occurred 27 times, one of these being purulent; 83 cases were regarded as functional disease. There were 14 instances of angina pectoris, 3 of tachycardia, 3 of bradycardia, 2 of Stokes-Adams syndrome; 4 cases were regarded as acute endocarditis, although no murmurs were found.

Of the 600 cases, we classify 444 as organic valvular disease. There are 92 cases classified as myocarditis, many of these having also mitral leakage or other valvular lesions. Of course, a great number of the cases of valvular disease were instances of endocarditis more or less active, but when murmurs were present the cases were placed under the valvular diseases. There were 10 cases of septic endocarditis.

One case was that of an unborn babe in which a systolic murmur was detected by Dr. H. G. Wetherill, and confirmed by myself and several other physicians. I have reported a similar instance previously. Four fatal cases are classified as dilatation from vagus paralysis, 3 of these from diphtheria and 1 from arsenical neuritis. There were 3 instances of Pick's disease. In 2 cases of transposition of the viscera, mitral leakage was regarded as of congenital origin, the murmur being systolic in time, loudest at the apex and transmitted toward the right, with accentuation of the pulmonic second sound in the usual place of the aortic valve. Both patients are still living.

A statement should be made as to the signs and symptoms which have led to the diagnosis of each of the valvular diseases mentioned. Aortic stenosis has been diagnosed only when a systolic murmur, to the right of the sternum, at the second space and upward, has presented an exceedingly harsh character and has been transmitted into the vessels of the neck, ordinarily accompanied by a systolic thrill. The aortic second sound is often weakened. Moderate hypertrophy on the left side of the heart should be present. The great majority of systolic murmurs here have been regarded as hemic or as due to roughening without material obstruction.

Aortic insufficiency has been diagnosed in cases presenting a diastolic murmur, generally blowing in character, heard at the aortic area and transmitted downward, and occasionally accompanied by a thrill. The direction and extent of transmission vary so greatly that less stress is laid on these features than upon the origin, time, and character of the murmur. The heart is usually enlarged. The aortic second sound is frequently absent. If the murmur originates at the center of the sternum or even to the left it has been regarded as of aortic origin if accompanied by Corrigan pulse, capillary pulse, or other clinical features of aortic regurgitation. Indisputable examples of relative leakage are given below.

Pulmonic stenosis has been regarded as present in the occasional cases which have presented rough systolic murmur and thrill to the left of the sternum, at the second interspace, the murmur transmitted to the midscapular region, sometimes more to one side than the other, presumably from predominating constriction in the branch of the pulmonic artery supplying that lung. The presence of pulmonary tuberculosis may be looked upon as a confirmatory sign, as in one case given, and marked lack of development is also commonly present.

Pulmonic regurgitation is certainly not a rare phenomenon if we seek for it carefully in those cases presenting great resistance in the lesser circulation. It has been diagnosed when a blowing diastolic murmur was present to the left of the sternum, transmitted downward, accompanied by dyspnea on exertion, and by enlargement of the right side of the heart, if signs of aortic leakage were absent. We should ask as confirmatory evidence the presence of some definite reason why we might expect this valve to leak, such as a history pointing toward congenital origin of the trouble, septicemia, as in one of my cases, or especially obstruction to the pulmonic circulation from fibroid disease of the lung or from advanced mitral stenosis, the latter being probably the most frequent cause. I believe that a dozen cases of relative leakage from the latter two causes may be found for every one of organic origin.

For the diagnosis of mitral stenosis we have sought for enlargement of the heart, especially transversely, the characteristic presystolic or diastolic murmur, often absent in time of broken compensation, presystolic thrill in many cases, accentuation of the pulmonic second sound, and frequently splitting of the basic second sounds. Dyspnea and pulmonary hemorrhage are often confirmatory. Extreme care has been taken as to this diagnosis when aortic regurgitation existed, and Flint's murmur has most often been diagnosed in these cases. In two instances, both lesions were confidently diagnosed, and in one of these the autopsy proved the diagnosis correct. The other patient was still living at last accounts.

Mitral regurgitation has been diagnosed when a blowing, occasionally musical, systolic or late sys-

*Read before the Denver County Medical Society, May, 1909.

tolic murmur has been found at the apex, transmitted to some extent to the left or upward, even toward the pulmonic valves in a few cases, occasionally accompanied by systolic thrill (probably only in cases of gross structural damage to the valves), with pulmonic accentuation, increase of heart area transversely, and oftentimes dyspnea, edema of the feet, dilated venules, and other commonly recognized signs of this disease.

In the present series I have not included scores of cases presenting transitorily such a murmur in the course of acute fever, after exertion, during the use of anesthetics, etc. Many clinicians formerly regarded murmurs of this type as hemic in character, and I formerly so believed and taught. Further study and experience lead us all, I believe, to regard this temporary relative mitral leakage to be one of the most frequent phenomena of disease, and undoubtedly of muscular origin. I doubt if such an apical systolic murmur is ever hemic. (See paper "The Cause of the Inconstancy of Mitral Regurgitant Murmurs," *Journal of the American Medical Association*, July 23, 1898.)

For the diagnosis of tricuspid stenosis a characteristic presystolic murmur should be heard at or near the fifth space to the right of the sternum, and, as the anatomical evidence tends to show, generally accompanied by, but distinct from, the signs of mitral stenosis. Presystolic thrill and marked cyanosis may be noted.

I have regarded tricuspid leakage as being present when a systolic murmur was heard at the tricuspid area, distinguishable from the murmur of mitral regurgitation, which is usually present, by its location, and generally by its softer character, and confirmed by systolic pulsation in the veins of the neck or in the liver. I regard the pulsation mentioned as much more reliable evidence than the murmur, the latter being, I believe, wholly unnecessary to the diagnosis in case the pulsation is characteristic.

The mitral valve was affected 385 times, the aortic valve 54 times, the tricuspid valve 13 times, and the pulmonic valve 16 times. Mitral regurgitation was found alone in 248 cases, mitral stenosis alone in 35 cases, aortic regurgitation alone in 11 cases. Aortic stenosis, tricuspid regurgitation, pulmonic regurgitation, and pulmonic stenosis were each found alone in one case. Tricuspid stenosis was not found in this series of cases, although I saw during this time one instance diagnosed by Dr. Henry Sewall, and proven post mortem. It was accompanied by mitral stenosis. The most frequent combination of two clinical lesions was that of mitral regurgitation and stenosis, of which there were 44 cases. Next to this came regurgitation at the mitral and aortic orifices, 31 cases. Mitral regurgitation and tricuspid regurgitation were noted in 8 cases. Mitral stenosis was associated with pulmonic leakage in 3 instances; mitral regurgitation and pulmonic stenosis were diagnosed in 3 cases; mitral regurgitation and aortic stenosis were found in 2 cases; aortic regurgitation with aortic stenosis was diagnosed in 1 case, although a systolic murmur was present in many cases without other signs of obstruction. Double mitral murmurs were found in association with tricuspid leakage in 2 cases; double mitral disease with aortic stenosis 1 case; double mitral disease with pulmonic regurgitation in 1 case; double aortic lesions with mitral leakage in 3 cases; in 1 case leakage was diagnosed at the aortic, mitral, and pulmonary orifices, and in 3 cases at the aortic, mitral, and tricuspid orifices.

In one case I regarded the trouble as being a mitral regurgitation with a double murmur at the pulmonic valve, apparently congenital, and probably organic. I have seen in a hospital case a double murmur at the aortic orifice, the same at the mitral, with tricuspid leakage, but in no case in this series were more than 3 murmurs fond in association. In 9 instances the murmur of mitral leakage was of the late systolic variety.

I found 7 cases of Flint's murmur. There were 5 instances of definitely musical murmurs, all mitral systolic in character. Palpable thrill was determined in 22 cases of mitral stenosis; in 11 cases of mitral regurgitation; in 4 cases of aortic stenosis; in 2 cases of pulmonic stenosis; in 2 cases of aortic regurgitation, and in 1 case of tricuspid regurgitation.

In the causation of valvular diseases we found that acute rheumatism is the predominating factor, as is generally believed, and that slightly more females than males were affected; 132 cases of mitral disease were of rheumatic origin; 17 of these cases of mitral were in conjunction with aortic disease, and 5 cases of aortic regurgitation were definitely rheumatic in origin.

Chorea was the cause of 20 cases of mitral disease, and 3 of mitral and aortic trouble. In addition, chorea occurred in 9 of the rheumatic cases given, and was associated once with tonsilitis, and once with scarlet fever, as the cause of valvular disease.

Scarlet fever was the cause of 22 cases of valvular disease, in 12 cases causing mitral regurgitation; in 2 cases mitral stenosis, and in one case double mitral disease. Mitral regurgitation and aortic regurgitation occurred twie; mitral regurgitation with tricuspid regurgitation occurred once; others unrecorded.

Pneumonia seemed the probable cause of valvular disease in 14 cases, in 9 of which the mitral valve was affected, in 1 the tricuspid being also affected; others not recorded. Myocarditis occurred twice; bradycardia once, and pericarditis was recorded twice as a sequel. It is certainly much more frequent during acute pneumonia than these figures would indicate.

In 11 cases of nephritis with valvular disease and without any other obvious cause, the vascular changes of this desease were regarded as responsible for the valvular trouble. Mitral regurgitation occurred 4 times; mitral and aortic regurgitation occurred once; aortic regurgitation with Flint's murmur once, while the remainder were apparently instances of relative mitral insufficiency. In 10 cases asthma was given as the cause, in only 4 of which was the trouble regarded as true mitral regurgitation. Asthma was present with an otherwise unexplained myocarditis 5 times, and 1 case was accompanied by angina pectoris.

Tonsillitis was the cause of 9 cases of valvular disease, in 6 of which mitral regurgitation was present, 2 of these being septic; aortic and mitral regurgitation occurred once; pericarditis with effusion occurred once, and adherent pericardium once. In 7 cases no cause could be found but a previous attack of typhoid. In 7 instances the general arteriosclerosis was looked upon as the responsible factor; 4 of these presenting apex systolic murmur apparently indicating mitral leakage. Six cases of valvu-

lar disease were evidently congenital; 5 cases originated in physical overexertion, 2 being in general athletes, 2 in wheel racers, and 1 in a long-distance runner. Diphtheria was the cause in 5 cases; measles in 2 cases. In 4 cases syphilis was followed by valvular disease, presumably through atheromatous changes. In 4 cases tuberculosis was named as the cause in the absence, upon careful inquiry, of any other.

The following diseases caused valvular lesions as indicated: gonorrhea, 1; erysipelas, 1; alcoholism, 3; sepsis, 2; infection following appendicitis, 2; diabetes, 2; empyema, 1; pertussis, 1; miner's phthisis, 1; mediastinitis, 1.

As causes of functional disease we find tobacco given in 36 cases; of these 4 were in females, 2 smoking, 1 chewing, and 1 using snuff. Tea or coffee was the obvious cause in 23 cases. A neurasthenic basis existed in 4 cases, while obesity apparently caused 6 cases, metrorrhagia 1, acetanilid habit 1, and oliguria 1.

A blood pressure exceeding 200 mm. (Riva Rocci) existed in 17 cases, 3 of these being respectively 300, 315 and 360 mm., all cases of nephritis, and the 2 latter dying within a few days from cerebral hemorrhage. In 6 of this list of cases the apparent cause was arteriosclerosis. Angina pectoris was present in several of the cases, as noted elsewhere.

Dropsy was noted as being of myocarditic origin in 53 cases and of valvular origin in 144 cases.

Hemoptysis was noted in 24 cases: it occurred 7 times among the 44 cases of double mitral disease—a proportion of 16 per cent. Among the 35 cases of mitral stenosis it occurred 5 times or 14.3 per cent, while among the 248 cases of mitral regurgitation it occurred 9 times or 3.6 per cent, and aortic regurgitation, myocarditis and asthma each caused hemoptysis once.

Hemiplegia occurred in 4 cases from cerebral thrombosis, 3 of these being right sided. From cerebral embolism there were 5 cases of hemiplegia, 3 being right sided and 2 left. Embolism also occurred at the bifurcation of the aorta once in a case of mitral disease, in the right leg once, in the right foot once, finger tip once, and in the pulmonary artery twice.

Albuminuria was noted in 54 cases, but doubtless occurred in many more at some stage of the disease.

In 20 cases of valvular disease in children, decided lack of growth was noted. In many of these cases the disease causing the valvular trouble had occurred during early childhood, and adherent pericarditis was a frequent cause of the loss of compensation and lack of proper growth. In 3 cases of septic endocarditis rupture of an aortic cusp was diagnosed and proven by autopsy in 2 of them. The diagnosis usually admits of no doubt. In 3 cases of myocarditis with extreme arteriosclerosis, intermittent limping was a prominent symptom.

Five cases of mitral stenosis, and one of mitral regurgitation, with hemoptysis were sent West upon a false diagnosis of tuberculosis; 1 case of mitral stenosis was sent West for asthma, and a case of aortic aneurysm was sent from New York City as one of asthma, the patient dying just after arrival.

Three cases of mitral disease from rheumatism were found in one family of five children, and the father had it also. One woman with valvular disease had lost her mother and grandmother from a similar cause. Certainly heredity is of some considerable importance, many instances of 2 cases occurring in the same family.

Although we have laid much stress upon the diagnosis of valvular lesions, we should emphasize the importance of the careful estimation of the muscular capacity of the heart, for this, and not the murmurs present, must be our guide in therapy as in prognosis.

In conclusion, I would state that I see no essential differences in the manifestations of cardiac disease here from those at sea level, excepting that compensation is more easily broken from a series of causes which I have considered at length in another paper entitled, "Cardiac Dangers in High Altitudes," in the *American Journal of the Medical Sciences*, March, 1909.

REPORT OF TWENTY CASES OF PULMONARY TUBERCULOSIS WITHOUT BACILLI IN THE BLOOD.

By L. ROSENBERG, M.D.,

BEDFORD STATION, N. Y.

At the suggestion of Dr. G. A. Fried, one of the attending physicians at the Montefiore Home Country Sanitarium, we undertook a number of blood examinations after the manner of Dr. Randall C. Rosenberger, in the hope of discovering, if possible, whether tubercle bacilli exist in the blood of individuals suffering from tuberculosis of the lungs. The investigations were made with the blood of twenty patients, in all but one of which the residue was inoculated into a guinea-pig. As a preliminary, Dr. Fried visited Dr. Rosenberger at his laboratory in Philadelphia and carefully familiarized himself with the various steps in the technique, which was faithfully followed by us in all our experiments.

To favor the chances of success as much as possible, we selected only such cases as had indubitable tuberculosis, with abundant bacilli in the sputum; four were in the so-called first stage, ten in the second, and six in the third.

In the smear from the blood of the fourth case examined organisms apparently identical with the tubercle bacillus were found, the slide being seen by four members of the staff. The pig inoculated with this blood was killed eight weeks afterwards and found perfectly normal, and careful examination of its blood failed to show anything resembling a tubercle bacillus. It should be mentioned, however, that this pig lost in weight in the last two weeks of life; this was also true of all the other inoculated animals, although they were allowed to live usually from ten to twelve weeks. No autopsy changes were found that could account for this loss of weight, and we are inclined to view it as a result of faulty care at this period, the man ordinarily in charge of this work being ill and the duty having been taken up by an inexperienced patient.

In one other case were acid-fast bacilli, or what looked like them, discovered in the blood of a patient. This was an acute case with stormy and rapidly fatal course, the blood being obtained just ante mortem. Unfortunately so little could be withdrawn that not enough remained for an animal inoculation; it was impossible to secure any blood post-mortem, so that this method of control failed us.

In some of the cases—nine to be precise—there were some slight changes found at autopsy of the

animals, mostly of a pigmentary nature; in all of these, smears from the viscera showing such changes were made, in addition to the regular blood smears, and were likewise found negative.

With the exceptions mentioned, no bacilli or other organisms were found, either in the patient's blood or in the blood of the guinea pigs, nor in smears made from the viscera of the latter.

Our investigations thus utterly fail to substantiate the contention of the originator of this method that tuberculosis is a bacteriemia. Our work was carried out with absolute fidelity to the instructions received, and, moreover, our subjects were all frankly infected with tuberculosis. The possibility of the contamination of the distilled water used in the making of the slides, very recently pointed out by the painstaking work of Walter V. Brem, offers a very plausible theory as to the origin and nature of the bacilli found in those cases in which the results were apparently positive.

A WRIST SUPPORT FOR SPHYGMOGRAPHIC TRACING.

By D. FELBERBAUM, M.D.,

NEW YORK.

HOUSE PHYSICIAN OF MONTEFIORE HOME.

ALL those who work with sphygmographs, or similar apparatus for the registration of the pulse, will agree that the most difficult part is the proper adjustment and fixation of the instrument. Once applied in the correct manner, it frequently happens that a slight movement on the part of the patient destroys the entire adjustment, and again requires prolonged manipulation to reattain it. Thus valuable time is lost, and this drawback is the chief factor causing the neglect of this mode of investigation in cardiac diseases, the more to be regretted, since within recent years simple and accurate instruments have been invented for clinical purposes.

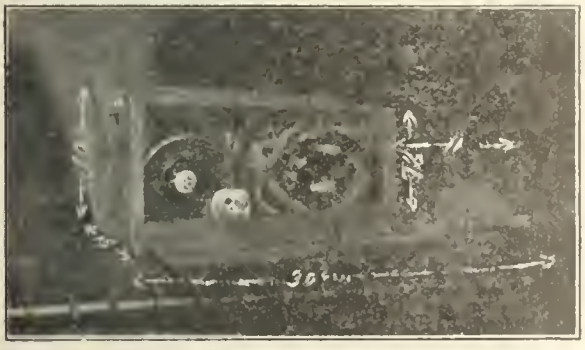

FIG. 1.—Showing apparatus, with door of compartment open, and cardiograph, tubing, etc. visible.

To obviate this difficulty and to facilitate the rapid obtaining of a sphygmogram, I have devised an appliance as illustrated herewith. It is made of wood, is compact, easily fashioned, inexpensive, and can be carried in a satchel. The base is 30 cm. in length, at one end of which a brass handle is placed; 11 cm. from this edge an upright is placed, the exact shape and measurements of which can be seen in Fig. 1. At the back is a second larger similar upright. The two are joined by side walls, one of which is hinged so as to form a door. In the compartment thus formed the various accessory paraphernalia for polygraphic records are stored. The apparatus is completed by two narrow slats, nailed across the two uprights, and forms the support for the forearm. At first I employed straps to hold the forearm in place, but found they were unnecessary, the forearm resting comfortably and permanently when the fingers grasp the handle (Fig. 2).

To operate, first get radial pulse (best to mark it with a pencil just above a little hollow, felt in front

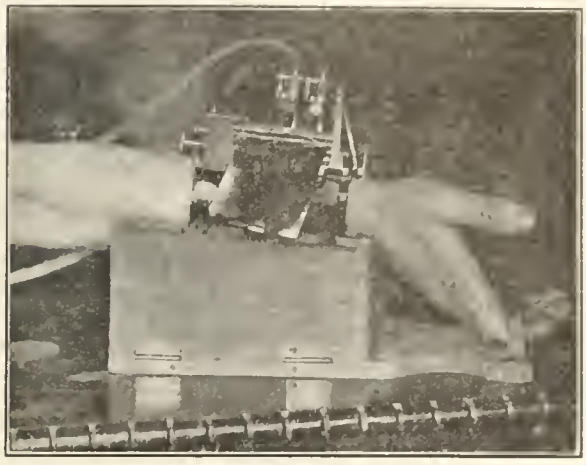

FIG. 2.—Showing apparatus in use.

of the styloid process of the radius), then apply the sphygmograph, and a little adjustment may be necessary in arranging the proper pressure. When once obtained, it remains.

With this hand rest the largest excursion of the lever and a uniform position are obtained. It saves time, is comfortable, and can be used for children also. It is light, cheap, and can be made even by a novice in carpentry.

ONE HUNDRED AND THIRTY-FIRST STREET AND BROADWAY.

The Nutrition of Typhoid Fever Cases by Way of Stomach and Rectum.—G. Franchini and F. Scordo have made very careful estimations of the results of metabolism in two patients subject to typhoid. One of them was affected with obstinate vomiting and was nourished by rectum to keep her alive. The other was an ordinary case of typhoid fever, and was fed by mouth. In the case fed by rectum there was a marked diminution in excretion of all the elements introduced by rectum. At the same time the enemata were not given very high, and were not well retained. There was deficiency of nitrogen, of fat, and of phosphorus, substances which are not absorbed by the large intestine. The vomiting and meteorismus diminished as well as the abdominal pain, and the mind of the patient became clear. It is evident that absorption is less by way of the rectum than by stomach, and hence we should feed our typhoid patients as far as possible by the stomach.—*Rivista Critica di Clinica Medica.*

Treatment of Diphtheria by Massive Injections of Antitoxin.—Delearde, Minet, and Bocquet advocate the use of much larger doses than are generally used of antitoxin, not only in severe cases of diphtheria, but in every case, no matter how mild. They believe that only thus shall we be able to forestall all the complications of the disease, heart failure and paralysis include. In every suspected case they would inject doses of 50 to 100 c.c. of the Roux serum. According to the condition of the patient as to temperature, albuminuria, circulatory or laryngeal complications is indicated the increase of the dose and its repetition. These doses are absolutely without danger to the patient, and cause no more erythema than the smaller doses usually given. Local treatment should be undertaken with a view to destroying the bacteria in the pharynx and keeping the upper respiratory passages antiseptic. The diet should be poor in chlorides, so as not to overburden the kidneys and to permit them to aid in removing the poisons. The most excellent results have been obtained by this method at the Hospital of Saint-Sauveur, at Lille. They seldom lose a case, and then only when brought under treatment after several days of sickness, and complications are unknown.—*Revue Française de Médecine et de Chirurgie.*

FOOTBALL AND THE MAN.

EACH year, at this season, from all quarters of the country, there appear in the editorial and correspondence columns of the daily press innumerable discussions of the game of football as played in our schools and colleges. These articles may well be divided into two distinct types: on the one hand the semihysterical, vituperative outpourings instigated by the latest injury or death on the athletic field, and on the other the defensive replies of the athlete, the coach, or the enthusiast. The one class insists that the game, as well as being dangerous to life and limb, is brutal and morally degenerating in its tendencies, and that it should be frowned upon by civilized society and prohibited by law, even as the prize fight and the bull fight are proscribed. A perusal of these articles, if they be taken seriously, must leave the impression that the American youth, if not maimed or killed outright, is in a fair way of being hardened, toughened, and made into a brute or a bully, with the one idea in life to attain his end by physical force, be the means fair or be they foul. Those taking the opposite view, and the technical knowledge displayed in their articles suggests that this class more frequently includes those who are personally familiar with the game, claim that it is no more dangerous than any other athletic sport. They call attention to the fact that the number of deaths is very small as compared to those from mountain climbing, from which eighty-four fatalities were reported in Switzerland during the past season, from yachting, swimming, riding, automobiling, or hunting. They further state that the game is necessary for the development of the best characters in the boy and the transformation into the highest type of man—that it brings out courage, dash, determination, and, above all things, cooperation, the characteristic which prevents a man exhibiting his own individual prowess and teaches him to work in unison with his fellows, each bearing his share of the labor that, by the concerted action of the whole, the best results may be attained.

The recent tragic death of Cadet Byrne and the crippling of Midshipman Wilson may be expected to result in long and serious discussions of the game at the next session of Congress. It is greatly to be hoped these discussions will be carried on in a quiet, impartial, and not a hysterical manner, and that, whatever be the decision, it will be arrived at as the result of calm, judicial weighings of the pros and the cons of the question. If football is good for the country and for the type of its manhood, it must remain; if it is injurious, it must either be so modified as to remove its objectionable features or it must go. The question to be decided is which of the elements, those tending toward good or those leading to evil, predominate. Such a question cannot be settled by expressions of individual opinion, but its solution must be based upon facts and figures, upon careful study of the remote results of the sport.

As it is but rarely played after graduation from college, and the players are scattered in all walks of life and to all parts of the country, statistics in regard to the results of university football are practically unattainable. We have, however, two institutions in which the game is played, and played exceptionally fiercely, the graduates of which are under constant surveillance to the days of their death, the United States military and naval academies. The records of the alumni of these two schools are very complete, and refer to physical efficiency, courage, mental qualities, and moral characters. It would seem that a careful analysis of the records of the officers of our army and navy might elucidate some facts of exceptional value in deciding as to the advantages and disadvantages of football. It would show whether the percentage of players later receiving recommendations for bravery or efficiency was above or below the average. It would give information as to the mental attainments of the football player as compared to the less athletic officer. By the behavior of the commander to his subalterns or his men some clue might be obtained as to the justice of the accusation that the game develops bullies and brutes. The records of reprimands, courts martial, and official inquiries might tell whether it tends more toward making the man into an animal or a gentleman, and last, but far from least, the records of the hospital corps would show whether or not the game tends to increase the officer's physical efficiency as a man and a soldier. We hear rumors of "football knees" giving out during forced marches, of tuberculous joints developing at the site of an old accident, and even of men being retired for general incompetency as the result of a previous injury to the head obtained on the gridiron. If such sequelæ of football do occur, the fact should be known, and if such ill effects are found to be numerous, it should argue strongly against the continuance of the game. As a simple question of national economy the government should not squander its thousands of dollars in making a man into an officer and then allow him, during the process of the making, wittingly to expose himself to an influence tending to render him useless for the purpose for which he is being prepared.

Such an analysis of army men should apply equally well to civilians. If the game makes better officers, it makes better men; if it incapacitates a cadet for his duties as a soldier, it may be expected to injure the student for his fight in the world of business. In such an investigation, however, it

must be borne in mind that it is quite possible that good or bad qualities developing in a man in later life may have been present or latent long before he took up the game, may even have been the factors which made him successful in it. The characteristic may have made the player, rather than the game the characteristic.

TECHINESS ON THE YELLOW FEVER QUESTION.

A VERY healthy state of sensitiveness has developed in these latter days, in regions where yellow fever once prevailed with more or less continuousness, to insinuations that the disease may still exist there, actually or potentially. Only a few years ago Havana would no more have resented the statement that yellow fever was endemic there than would or could New York that pneumonia prevails here, but to-day it repels any such insinuation with more than tropical heat. A few months ago it was said in these columns that there was a belief that some cases of yellow fever had occurred in Cuba recently. The statement was founded on the report of a trustworthy correspondent and was partially supported by a report made by a committee of the Louisiana Board of Health, the committee giving as their belief that a suspicious case at Caibarien was actually one of yellow fever. The statement, however, was the occasion of some vigorous language in the Havana press and was also vehemently denied by the health officials, whose indignation was quite comprehensible and under the circumstances justifiable.

Now one of these same officials has been made the subject of some far from complimentary resolutions by the Louisiana Board of Health. In an interesting paper read before the International Congress at Budapest and published in the MEDICAL RECORD of September 4, Agramonte described the methods employed by the Cuban officials in dealing with any suspicious or declared case of yellow fever, methods which, if carried out, give assurance that the disease can never again establish itself on the island. Unfortunately in closing his article, the author indulged in some comparisons, which are proverbially odious if not odorous, reflecting upon present conditions in New Orleans. In that city, he said, the authorities had failed to maintain the necessary screening of the water cisterns, with the result that "mosquitos are to-day nearly as plentiful as before the dreadful epidemic of 1905." The Cubans, by the way, attribute the reappearance of yellow fever in their island, after its extirpation by Gorgas, to importation from New Orleans. These remarks of Agramonte were brought up at a meeting of the Louisiana Board of Health on October 15, and made the subject of some uncomplimentary comment, and a resolution was passed to the effect that the objectionable statement was, "as a whole, entirely false and acrimonious as it related to conditions in the State of Louisiana and the city of New Orleans." We quote from the *Picayune's* account of the meeting of the State Board.

The sensitiveness betrayed by both Havana and New Orleans is somewhat amusing. It is also reassuring in its proof of a self-consciousness in regard to health matters which gives promise of continued vigilance. So long as such techiness continues outsiders may feel a reasonable sense of security that yellow fever will not be allowed to gain a foothold again either in Havana or in New Orleans. We wish we had as good reason to congratulate ourselves in regard to the Mexican coast towns and certain other cities of our Southern littoral.

THE EARLY DIAGNOSIS OF MEASLES.

THOUGH there is a well-grounded belief among the laity that measles is of little more importance than a common cold, that every child must have it sooner or later, and that the grandmother is the best authority on the treatment, to the physicians in charge of children's hospitals and especially those hospitals in which there are many cases of latent tuberculosis the prospect of an epidemic of this disease is a cause of no small alarm. It is in such institutions that the fatal sequelæ of this mild malady are most frequently seen, and it is there that any means of diagnosing the disease before it has reached the stage of contagiousness would be of inestimable value, for as a rule by the time a child in such an institution has developed the rash it has infected every other inmate of the ward.

The discovery by Koplik of the spots in the mouth, one, two, or even three days before the appearance of the eruption, was hailed with enthusiasm, and has resulted, in innumerable instances, in the correct diagnosis and the segregation of the patients many hours or even days earlier than would otherwise have been possible. The discovery of the spots is, however, a test of but comparative value in the prevention of an epidemic of measles, as, even if they are seen within a few hours of their appearance, the child has probably already had sufficient time to infect its neighbors. In the face of the great contagiousness of the disease among children the diagnostic sign which is needed is one appearing early in the prodromal period before the patient has become dangerous to his fellows. In the *Münchener medizinische Wochenschrift* for October 12, 1909, Hecker presents a report of the blood changes in the early stages of measles which he believes in certain instances may be of value in giving information of the approach of the attack. He has found that several days prior to the appearance of the Koplik spots, the blood begins to show a distinct reduction of the total number of leucocytes, an absolute leucopenia, occasionally varied by a transient leucocytosis, marked rapid changes occurring from day to day in the leucocyte count. Especially constant is the appearance of a reduction of the lymphocytes from three to five days before the Koplik spots show themselves. The lymphopenia is absolute, being due to an actual reduction of the lymphocytes and not to a leucocytosis. This premonitory leucopenia and lymphopenia, the author believes, may prove of value in the foretelling of approaching measles, and in enabling early and adequate quarantine precautions.

The application of a test of this kind must from its

very nature be extremely limited, and still occasions may easily be imagined in an institution in which there is a suspicion of recent exposure to measles, when systematic blood examinations of the suspects would be eminently worth while, if thereby the infected children might be isolated sufficiently early to prevent a widespread epidemic of the disease.

Intrauterine Child Culture.

Child culture is the fashion to-day, and it is well that it should be so. We have no right to let the child grow up as best he can. After he has been brought into this world, without any volition of his own, it is our duty to give him a fair chance to grow up a strong, healthy, well-balanced individual. But do we give him such a chance if he comes into this world crippled for life by lack of strength, or the possession of some diathesis that will hamper him through life? Child culture, then, must begin before the birth of the child, while he is *in utero*, must even begin with the parent before the conception of the child. This is, of course, an argument for the regulation of marriage, so that the partners for life will be well matched physically, and will not transmit an hereditary taint to their offspring. In the *Journal de Médecine de Paris*, for September 11, 1909, Professor Oui of the Lille Faculté, directs our attention to the best methods of intrauterine puericulture. There are many parents, he says, who have no knowledge of anything that concerns the perpetuation of the species, and their responsibilities to their children, and he believes that we should discard all false modesty, and have the physiology and anatomy of the functions of reproduction taught in every school, rather than leave children to the garbled knowledge which they may obtain from their companions. The pregnant woman, whether married or not, should be cared for by the State, so that she is given a fair chance to bring forth a healthy child. At present the unmarried mother is left to the deepest poverty. The State should care for her, and should place her under the care of a physician or midwife, if she be too poorly placed to care for herself. Rest is necessary during the last months of pregnancy to give the child full development. In a small municipality in France, Villiers, where the mayor happens to be a physician, between the years 1894 and 1903 but one still-born infant was registered, while the nearby towns have registered three times as many. Insufficient feeding of the pregnant woman has much to do with the interruptions of gestation in the poor. The most unfavorable influence that exists during late pregnancy is the necessity of working in a standing position, as must be done by the poor woman who must work to support her family. For the last two months she should have comparative rest. The remedy for these evils, Oui maintains, is the care of pregnant women by the State, and the establishment of refuges where the unmarried may be cared for properly, thus preventing crime and illness, and lessening the number of weak, undeveloped children who are brought into the world.

Rectal Injections of Salt Solution in Pylorospasm.

A few weeks ago attention was called to the work of Engel of Düsseldorf upon the physiology of the so-called congenital pyloric stenosis or pylorospasm of infants, by which he was able to show that, in certain of the cases at least, the etiological factor of the disease was a marked hyperacidity or hypersecretion of gastric juice, possibly secondary to a congenital neurosis. It was further pointed out that an early diagnosis of the condition might possibly be obtained by an examination of the gastric contents of the vomiting infant for hyperacidity, and that a rational therapeusis based upon a knowledge of the hyperchlorhydria might offer hopes for better results in the treatment of this too commonly fatal disease. In the *Deutsche medizinische Wochenschrift* for October 14, 1909, Rosenhaupt offers a suggestion as to the method of reducing the acidity in such cases. Referring to the recent work of Benczur on dogs, by which the latter found that the injection into the rectum of a considerable quantity of a four per cent. sodium chloride solution caused a marked decrease in the amount of secretion of gastric juice, the writer offers the suggestion that the same procedure be used upon infants who suffer from pylorospasm. He further states that it has long been his custom in all of his cases of pylorospasm, in order to keep up the body fluids, to give salt solution per rectum, and he now believes that his remarkably good results with the disease, he having had but one fatality, are due to the specific action of the rectal saline in reducing the gastric secretion. The suggestion would seem at least to be based on a physiological foundation and, in the light of Rosenhaupt's results, upon clinical experience.

Serum Therapy of Typhoid Fever.

Competent workers have gradually come to the conclusion that no antitoxin comparable to that used in diphtheria can ever be made for typhoid fever. The excitant of the latter disease causes a septicemia soon after onset, produces no soluble poison, and leads to local lesion only in the later stages of the affection. However, many men have attempted to produce curative sera by using the dead bodies of the bacilli themselves, believing that the contained endotoxins may give rise to immune bodies in inoculated animals. In the *Wiener klinische Wochenschrift* for October 14, 1909, Drs. Kraus and Stenitzer report the results from the use of such a serum in an epidemic of typhoid fever among soldiers. Thirty-three cases were treated, only five of them being clinically of light character. The four deaths in the series, while apparently making the mortality very high, were caused by such complications as perforation, aspiration pneumonia, empyema, and septic nephritis, rather than by the toxemia of the typhoid fever itself. The effect of the serum, on the other hand, was very apparent. Given at a time when the temperature was gradually rising, it led to a drop in the fever, occurring very soon or in a few days after its administration. This therapy led to marked shortening of the febrile course of the disease and to great improvement in the subjective symptoms. In no case were any untoward symptoms noticed beyond harmless exanthemata so frequently seen in serum therapy. Experimentally, it was shown that the serum used in these cases could neutralize typhoid endotoxins introduced into the bodies of susceptible animals. These results are, of course, very modest; yet they show that the situation is not as hopeless as other workers in the field have tried to make it out. Specific therapy in typhoid fever is a possibility, though its results are far below those obtained with sera in some other infectious diseases.

News of the Week.

Model Tenements for Tuberculosis.—Plans have been filed at the office of the Building Superintendent of New York for the construction of four fireproof model tenements to be built on Avenue A, between Sixty-seventh and Sixty-eighth streets, for the occupancy of families in which one or more members is a sufferer from tuberculosis. The project is a philanthropic enterprise of Mrs. W. K. Vanderbilt, the plans being carried out under the supervision of Dr. Henry L. Shively of the Presbyterian Hospital. Each building will have sixteen suites for small families on each floor of two, three, four, and five rooms to the suite, offered at moderate rents and arranged to accommodate from 350 to 375 families. They will be only a short distance from the site of the new Presbyterian Hospital. The novel feature will be the series of open staircases leading from the central open courts, giving to the occupants facilities of entering the separate apartments directly from out of doors. Each building will have four of these staircases, and they are designed as a special protection against the spread of the disease. There will be no common hallways, no dark corridors, and no place for dirt and dust to accumulate. A second novelty of construction will be the open air wards on the roofs, after the manner of some of the city hospitals, corresponding to what are now called day camps for open air treatment of tuberculosis. There will be small roof gardens, steamer chairs, and separate toilet chambers for men, women, and children, the idea of the owners and architect being to encourage to the fullest extent outdoor living for the tenants. The third new departure from the ordinary type of model tenement will be the series of balconies on each house so that the tenants may eat and sleep in the open air. The windows opening upon these balconies will be in three sections, capable of opening from floor and ceiling, and thus making the balconies actually part of the regular sleeping quarters. The buildings are to cost $650,000 exclusive of the sites.

Tuberculosis Hospital for Montreal.—At a recent meeting of the Finance Committee of Montreal it was voted to construct a new civic hospital for tuberculosis, and plans were ordered to be prepared. It is estimated that the new hospital will cost $150,000.

Private Tuberculosis Sanatorium for Catholic Sisters.—A private sanatorium for the treatment of tuberculosis is to be established at Mt. St. Michael's Seminary, Hyde Park, two miles north of Reading, Pa., on a tract of fifty-two acres of rich, cultivated farm land at an elevation of 600 feet above sea-level. The institution will be devoted exclusively to the treatment of tuberculosis in sisters teaching in the Catholic parochial schools of the State of Pennsylvania.

Red Cross Stamps.—The American Red Cross Society has just made the announcement that the Red Cross Christmas Stamp is soon to be placed on sale in all parts of the Union. The stamp is of an attractive design selected from 1,200 submitted in competition. The Society has already ordered 30,000,000, but it is expected that 50,000,000 will be sold by Christmas. These stamps will be used as "stickers" on gifts, packages, and letters during the holiday season. Mr. Ernest P. Bicknell, Director of the American National Red Cross, states "that in 1908 the Red Cross Christmas stamps were sold in thirty-five States and Territories, and $135,000 to be devoted solely to forwarding antituberculosis work was the result."

New Antitoxin Rules in Chicago.—The Chief Medical Inspector announces new arrangements for the distribution of diphtheria antitoxin, as follows: Antitoxin for the treatment of diphtheria is now furnished by the State of Illinois free to any physician who will apply at any of the new distributing stations established in Chicago by the State Board of Health. To procure free antitoxin the doctor must apply in person at the distributing station and sign a receipt for the amount furnished, or he may write a prescription for the amount required and send a messenger for it. A clinical report must be filled out and signed by the doctor when the case of diphtheria is terminated. This clinical report must be mailed to the laboratory of the State Board of Health, Springfield, Ill. The city has ceased buying antitoxin and has discontinued furnishing it through the police stations. Culture outfits, however, will be kept in the police stations as heretofore.

The Beneficent Effects of Diphtheria-Antitoxin.—From the report of the Pennsylvania State Department of Health it appears that free antitoxin was distributed among the poor in 15,428 cases of diphtheria from October, 1905, to January, 1909, with 14,080 recoveries, or 91.26 per cent. In addition 10,253 persons were given immunizing doses of antitoxin. All but 161 of these were protected, and of those that contracted the disease 10 died. The State Department of Health has 650 distributing stations throughout the State where at all times physicians can secure free antitoxin for indigent persons.

Freed from Leper Colony.—The assertions of several medical experts who have recently visited the Molokai leper colony, near Honolulu, that many of the unfortunates are not lepers were proven when fifty out of the first hundred patients to be examined by a special commission of physicians were found free from all taint of the disease. There are 875 lepers on the island and all will be examined under the recent law passed by the Legislature. All the examinations are bacteriological and very thorough. All who do not show plainly the ravages of leprosy will be submitted to examination.

The Beaumont (Texas) Chamber of Commerce has formed a civic improvement committee which is turning its attention to public hygiene to the extent of publishing and distributing a series of small pamphlets on this subject.
